The macroscale movement behavior of a wide range of isolated migrating cells has been well characterized experimentally. Recently, attention has turned to understanding the behavior of cells in crowded environments. In such scenarios it is possible for cells to interact, inducing neighboring cells to move in order to make room for their own movements or progeny. Although the behavior of interacting cells has been modeled extensively through volume-exclusion processes, few models, thus far, have explicitly accounted for the ability of cells to actively displace each other in order to create space for themselves. In this work we consider both on- and off-lattice volume-exclusion position-jump processes in which cells are explicitly allowed to induce movements in their near neighbors in order to create space for themselves to move or proliferate into. We refer to this behavior as pushing. From these simple individual-level representations we derive continuum partial differential equations for the average occupancy of the domain. We find that, for limited amounts of pushing, the comparison between the averaged individual-level simulations and the population-level model is nearly as good as in the scenario without pushing. Interestingly, we find that, in the on-lattice case, the diffusion coefficient of the population-level model is increased by pushing, whereas, for the particular off-lattice model that we investigate, the diffusion coefficient is reduced. We conclude, therefore, that it is important to consider carefully the appropriate individual-level model to use when representing complex cell-cell interactions such as pushing.

I. INTRODUCTION

Cell migration is an integral feature of many developmental and homeostatic mechanisms, including embryo formation [1], wound healing [2], and immune response [3]. In addition, cell migration is critical for the development and progression of pathologies such as cancer [4], vascular disease (e.g., atherosclerosis [5]), and chronic inflammatory diseases (e.g., arthritis [6]).

Many of the mechanisms postulated for the migration of individual cells have been well characterized in an experimental setting [7,8]. Recently, attention has turned to studying cell migration mechanisms for cells in densely crowded environments in which cell-cell contacts are inevitable. In such environments it is possible for cells to interact in order to facilitate movement or proliferation. In particular, in in vitro experiments cells have been shown to facilitate their movement or proliferation into a region currently occupied by a neighboring cell either crudely, by exerting direct force upon their neighbors, or more subtly, through contact-mediated rearrangement of a neighboring cell’s actin-cytoskeleton leading to its dispersive migration [9].

Cells have also been shown to exert pushing forces on their surroundings [10]. Over-crowded groups of cells in developing epithelia have been shown to extrude cells from the epithelial sheet in order to make more room for themselves to move and proliferate into [11,12]. Collective motion of cells, in part mediated by cell-cell pushing, has also been demonstrated to be important for normal development [13] and for the progression of pathologies such as cancer [9,10]. Vroomans et al. [14] employ a cellular Potts model to infer that the pushing of desensitized cells by T cells sensitive to a chemoattractant is a possible explanation for the high scanning efficiency of antigen-presenting dendritic cells in the immune system. Throughout the remainder of this paper we will refer to any contact-mediated action initiated by one cell in order to displace another to make room for itself or its progeny as a “push.”

Cell migration and proliferation have been modeled extensively at both the population-scale, in which deterministic partial differential equations (PDEs) are typically employed to model the density of cells [15–18], and at the cell scale, in which each cell is modeled as an individual [19–25], often using in silico techniques to simulate the dynamics of the model. Both modeling regimes have their advantages and disadvantages (for a more detailed discussion of these see, for example, Yates et al. [25] and Baker et al. [24]). Several previous works have addressed the derivation of continuum models from individual-based models in which cell-cell displacement is implicitly incorporated via “hard-core” interactions or pairwise potential interactions [26–30]. In this paper, beginning with individual-level models (ILMs) that contain descriptions of the biological processes described above (including migration, proliferation and explicit cell-cell pushing), we derive population-level models (PLMs) for the evolution of the expected domain occupancy which can be thought of as being equivalent to the mean-field behavior of the ILM in an appropriate limit.

We consider two variants of the ILM, on- and off-lattice. and use a flexible master equation formalism to derive the corresponding PLM in each case. Although ILMs
of cell migration and proliferation and their continuum limits have been investigated previously [19,22], in this work we incorporate the ability of cells to displace neighbors which, in a classical exclusion process, would restrict movement or proliferation. We discover that the PDEs derived from the on- and off-lattice ILMs in the continuum limit have qualitatively different behavior: In on-lattice models we find that pushing enhances the effective diffusion coefficient of the corresponding PDE, whereas, with off-lattice models, we find that the diffusion coefficient is reduced. We provide explanations for this disparity and emphasize that it will have important ramifications for model selection when attempting to represent biological phenomena that involve cell-cell pushing.

The remainder of this paper is structured as follows. In Sec. II we describe, in detail, the elementary on-lattice ILM for cell-cell pushing. From this simple model we derive an equivalent population-level PDE model and, through numerical simulation, demonstrate the importance of incorporating cell-cell pushing on the population-level behavior of the cells. In Sec. III we incorporate more complex cell pushing mechanisms in the ILM. From these models we derive and interpret the corresponding set of PDEs that result when the appropriate continuum limit is taken. We present comparisons between the ILMs and the PLMs and comment on the causes of any disparities. We introduce the off-lattice ILM in Sec. IV and demonstrate the resulting PDE has some unexpected properties (in comparison to the corresponding PLM derived from the on-lattice model). We conclude in Sec. V with a discussion of our findings and suggestions of areas which merit further exploration.

II. THE IMPORTANCE OF CELL PUSHING

In this section we introduce the basic on-lattice ILM and subsequently build its complexity by incorporating the ability of cells to push one another in a simple manner. Using a master equation formalism we then derive the corresponding PLM for pushing and compare the cell density generated by this model to the expected cell density averaged over several repeats of the ILM.

A. On-lattice individual-level model

Initially we model cell migration and proliferation using a simple on-lattice, two-dimensional exclusion process in which each cell is represented by a single autonomous “agent.” In an exclusion process, at most one agent can occupy each lattice site. We consider a square lattice [i.e., the lattice spacing is the same (Δ) in both directions] with Lx sites in the x direction and Ly sites in the y direction. Since an agent exclusively occupies a single lattice site, Δ can be thought of as equivalent to the diameter of the cells under consideration. The occupancy of the lattice site with index (i, j) and position (x, y) = (iΔ, jΔ) is denoted C(i, j). If lattice site (i, j) is occupied, then C(i, j) = 1, otherwise C(i, j) = 0. We initialize N agents on the lattice and the occupancies of the lattice sites change in discrete time in the following manner. At each time step, of duration τ, N agents are chosen uniformly at random, sequentially, and with replacement. Selected agents attempt to move to one of their four nearest-neighbor lattice sites with “movement probability” Pm ∈ [0, 1] [19,20,31,32]. If the site into which an agent attempts to move is occupied, then that movement event is aborted. Note that sampling with replacement allows one agent to move multiple times during a single time step and also for agents not to move at all. In what follows, we choose lattice spacing Δ = 1 and time step τ = 1, noting that both time and space can be rescaled in order to deal with specific experimentally derived parameters.

In the traditional exclusion process model, if an agent attempts to move or proliferate into an occupied lattice site, then that event will be aborted. In this work we relax this assumption by allowing agents to push each other out of the way in order to complete a movement or proliferation event into a currently occupied lattice site. In the most basic case [see Fig. 1(b)] we allow an agent at position (i, j) which has chosen to move rightward into an occupied site (i + 1, j) to push the agent at (i + 1, j) to the right into site (i + 2, j), with “pushing probability” Qm, providing that site is unoccupied. If the site (i + 2, j) is occupied, then, in this most basic case, the movement event is aborted (although we relax this condition later).

In Fig. 2 we present snapshot comparisons of the lattice occupancy of the exclusion process model described above, both with and without pushing, in the absence of proliferation. Some simple but informative observations can be drawn from this figure. It is evident by later times [cf. Figs. 2(c) and 2(f)] that the agents that are allowed to push are more evenly spread than those that are not, with fewer large clumps of agents evident. This is to be expected as pushing agents that are clumped together are more likely to undergo successful movement events in comparison to their nonpushing counterparts, leading to the accelerated breakup of such clumps. Perhaps surprisingly, the positions of the leading edge of the groups of agents do not differ a great deal and, after initially diverging [cf. Figs. 2(b) and 2(e)], appear not to diverge more over time [cf. Figs. 2(c) and 2(f)]. This hints that, after an initial transient, the position of the leading edge is dictated primarily
parameters are exclusion process model with agent-agent pushing (\(Q^m = 1\)) of the domain (1 \(\leq x \leq 100, 40 \leq y \leq 60\)) at each site of the lattice. Let \(C_n(i,j)\) denote the occupancy of site \((i,j)\) at iteration \(n\) in the \(r^{th}\) repeat (of a total of \(R\) repeats) of the simulation. We define the average occupancy of site \((i,j)\) at iteration \(n\) as

\[
C_n(i,j) = \frac{1}{R} \sum_{r=1}^{R} C^r_n(i,j). \tag{1}
\]

By considering the possible ways the average occupancy of site \((i,j)\) could have changed over the course of a time step and assuming that site occupancies are independent, we can write down the following PME for the exclusion process with agent-agent pushing\(^1\):

\[
C_{n+1}(i,j) - C_n(i,j) = -\frac{P^m}{4} C_n(i,j)[(1 - C_n(i + 1,j)) + (1 - C_n(i - 1,j)) + (1 - C_n(i,j + 1)) + (1 - C_n(i,j - 1)) + Q^m[C_n(i + 1,j)1 - C_n(i + 2,j)] + C_n(i - 1,j)(1 - C_n(i - 2,j)) + C_n(i,j + 1)(1 - C_n(i,j + 2)) + C_n(i,j - 1)(1 - C_n(i,j - 2))] + \frac{P^m}{4}(1 - C_n(i,j))(C_n(i + 1,j) + C_n(i - 1,j) + C_n(i,j + 1) + C_n(i,j - 1) + Q^m[C_n(i + 1,j)C_n(i,j + 2,j)] + C_n(i - 1,j)C_n(i - 2,j) + C_n(i,j + 1)C_n(i,j + 2) + C_n(i,j - 1)C_n(i,j - 2))]. \tag{2}
\]

\(^1\)Note that in the first instance we ignore the effects of agent proliferation for simplicity but derive the corresponding continuum equation with proliferation later.
The terms that only have prefactor $P_m$ correspond to occupancy changes due to simple movement, whereas those with additional prefactor $Q_m$ correspond to occupancy changes related to movement-induced agent-agent pushing. For simplicity, we ignore proliferation in this PME, but note that it is straightforward to incorporate into the PME (and the following derivation) in a similar manner.

We make the simplest of moment closure assumptions: that site occupancies are independent. This assumption can be justified in certain circumstances [19,21,32]. Indeed, we find that for the case of basic agent-agent pushing, presented here, the PLM derived under the independence assumption agrees that for the case of basic agent-agent pushing, presented here, the corresponding PDE (3) in one dimension.\(^2\) The correspondence between PLM and averaged ILM is good in both cases [although marginally better for simple diffusion than for pushing (see Fig. 7 for a quantitative comparison)]. As noted by considering the density profiles of the ILM the incorporation of pushing reduces peak density levels by facilitating the movement of cells away from areas of high density. This might have been predicted from Eq. (3) since the incorporation of agent-agent pushing increases the effective diffusion coefficient by adding a term proportional to the pushing probability, $Q_m^n$. This term is also density dependent, intimating that the effect of pushing will be greater when the agent density is higher and less noticeable when agent density is lower, for example, at the leading edge of the profile. This density-dependent phenomenon is consistent with our previous observation, from the ILM, that the positions of the leading edge of agents in the model with and without pushing do not differ greatly.

In order to gain a greater insight into the possible biological effects of cell-cell pushing we now generalize the types of interactions that agents can undergo with their neighbors in the ILM and consider the effect these changes have on the resulting PDEs.

### III. EXTENSIONS TO THE PUSHING PARADIGM

It seems unreasonable, perhaps, to restrict pushing agents to moving neighboring agents only in their direction of movement or even for agents to be able only to move a single neighbor out of the way. We now explore the effects of relaxing these restrictions. In what follows each of the PDEs derived will be of the general form

$$\frac{\partial C}{\partial t} = \nabla \cdot [D(C) \nabla C] + \lambda S(C),$$

where $D(C)$ represents an effective diffusion coefficient and $S(C)$ a source of agents due to proliferation. We summarize these coefficients for each variant of the model in Table I. Note

---

\(^2\)In order to solve each of the PDEs presented in this work we use a finite difference discretization in space with spacing $dx = 0.1$ and a semi-implicit time discretization with time step $dt = 0.1$. The resulting nonlinear system is solved using Picard iteration with a tolerance of $\varepsilon = 10^{-8}$.
The PME for these cases become extremely lengthy and, as such, we omit them from the main text but refer the interested reader to Sec. IA of the Supplemental Material (SM) [33]. In Figs. 5(a) and 5(b) we present a comparison of the column-averaged ILM and the corresponding PDE for type I and type II adjacent pushing, respectively. In both cases the agreement between the ILM and the corresponding PDE is good, although it is slightly better in the case of type II adjacent pushing.\(^3\)

For type I adjacent pushing the peak density is not reduced as rapidly as it is for basic pushing [cf. Figs. 3(b) and 5(a)]. Considering the possible pushing movements from the step-function initial condition provides some insights. An agent which is one column away from the front of the initial distribution attempting to move towards the front will now only do so (by pushing an agent at the front to the right) with probability $Q^m/3$, whereas in the basic pushing case it would do so with probability, $Q^m$. There is some compensation for the type I adjacent pushing process in that an agent on the front which attempts to move vertically (either up or down) will now do so (displacing the neighboring agent, whose site it moves into, out of the front in the horizontal direction) with probability $Q^m/3$. In the basic pushing model these two moves would be aborted. However, we note that moves of this sort only provide a net movement of one agent in the horizontal direction in comparison to the net movement of two agents in the event of agents pushing from the column behind the front. This helps to explain why spreading is retarded in the type I adjacent pushing model.

In contrast, peak density in the type II adjacent pushing model decreases more rapidly than in the basic pushing case [cf. Figs. 3(b) and 5(b)]. In an analogous manner this is due to the completion of more successful pushing events; any proposed pushing event in which the pushed agent has at least one empty neighbor will be completed with probability $Q^m$ in contrast to the type I adjacent and basic pushing models in which some of these pushing events will be aborted.

### B. Pushing multiple agents in a line

The next extension we consider is to allow a pushing agent to push up to $K$ other agents in a straight line in a chosen direction (see Fig. 6). For each attempted push of $k \leq K$ agents we introduce a probability of acceptance $Q^m_k$.

The PME is, unsurprisingly, considerably more complicated than in the basic pushing case and as such we present it in Sec. I B of the SM. In the usual diffusive limit, upon taking the Taylor expansion about point $(i,j)$, as before, we arrive at the PDE specified by Eq. (6) and the coefficients in the final row of Table I. The independence assumption that we employ in order to write down the PME [see Eq. (2) of the SM] becomes progressively invalid as the number of agents that a pushing agent can move out of the way increases. Clearly, such

---

\(^3\)Note that in all the comparison figures we give, we deliberately omit proliferation so the effect of pushing can clearly be discerned. However, we note that the effect of pushing due to proliferation is similar to the effect of pushing due to movement, as evidenced by similar alterations to the functional form of the diffusion and source coefficients for the different pushing cases given in Table I.
domain specifications, boundary conditions, and initial conditions are as in Fig. 2. All individual-level results are averaged over 100 repeats.

pushing events introduce correlations between occupancies of both neighboring and non-neighboring lattice sites. This leads to a divergence between the mean occupancy in the ILM and the occupancy predicted by the PLM that we derive and the averaged individual model results to be as good as in the basic pushing case. This is borne out in Fig. 5(c) where we compare the column-averaged ILM and the corresponding PDE for linear pushing with the possibility of pushing at most two agents (i.e., $K = 2$). The agreement between the models, although slightly worse than the basic pushing case, is still at a good (see Fig. 7 for quantification).

As we increase the number of agents that a single agent can push out of the way, the comparison between the PLM and the averaged ILM becomes increasingly poor (see Fig. 1 of the SM). We note that there are a variety of methods for obtaining more accurate PLMs (among them higher-order moment closure and spatial correlation functions [34,35]), but we do not discuss them further in this manuscript.

C. Error comparison

In order to quantify the error between the ILM and the PDE in each of the above cases, we compare averaged simulations of the ILM with the numerical solution of the PDE. Our metric of choice is the histogram distance error (HDE) [25,36,37]:

$$H(t) = \frac{1}{2} \sum_{i=1}^{L_x} \left| a_i(t) - b_i(t) \right|,$$

where $a_i$ and $b_i$ denote the values of the (normalized) column-averaged occupancies (averaged also over several repeat simulations) of the on-lattice exclusion process and numerical solution of the PDE, respectively, at column $i$ and time $t$.

Figure 7 compares the evolution of the HDE for each of the above outlined cases. It is clear to see that our qualitative conclusions based on a by-eye comparison of the density profiles are borne out quantitatively by the HDE comparison. The scenario with the lowest HDE is, as expected, simple diffusion, and the scenario with the worst comparison to its “corresponding” PDE is the case of linear pushing of multiple agents.

We have presented results for an intermediate, representative value of the pushing probability, $Q_m = 0.5$. However,
we have also carried out comparisons for lower probabilities of successful pushing ($Q^m = 0.1$) and higher probabilities ($Q^m = 1$). The qualitative trends observed are similar for each value of $Q^m$ that we considered, however, the HDE for the pushing cases was elevated when $Q^m$ was increased and correspondingly reduced when $Q^m$ was decreased, as might reasonably be expected (see Fig. 2 of the SM). The same qualitative results are observed for the different on-lattice pushing mechanisms (results not shown).

Thus far we have considered on-lattice ILMs of cell migration. However, in reality cells do not migrate on a regular lattice. In the next section we will relax the on-lattice assumption and explore the possibility of incorporating pushing into off-lattice models of cell migration. In particular we will explore how changing the ILM affects the corresponding PLM.

### IV. OFF-LATTICE INDIVIDUAL-LEVEL MODEL

The lattice-based models considered provided us with a convenient formalism to incorporate agent-agent pushing into an ILM of cell migration, which was then used to derive a PLM in the form of a PDE. However, although simple to formulate, these ILMs make the important assumption that movement and proliferation events can be restricted to an artificially imposed lattice structure. This limitation is clearly an important one and it has been shown that on-lattice models can introduce artifacts that are not present in the underlying biology [38].

It makes sense, therefore, for us to consider how the effects of agent-agent pushing are altered in an off-lattice exclusion-process model of cell migration. These models are typically overlooked because of the increased complexity of their simulation and the increased mathematical complication when attempting to derive a corresponding PLM. However, recently,
some excluding off-lattice models have been postulated. These models focus on considering the effects of diffusion [22,27,39] and proliferation [40], but none thus far have considered the effects of agent-agent pushing.

When formulating the ILM and deriving a corresponding PLM we follow the approach of Dyson et al. [22] and Dyson and Baker [23]. We consider $N$ agents of radius $R$ on a line of length $L_x$. Agents are initially positioned so the gap between the centers of two adjacent agents is uniformly distributed on $[2R,12R]$. With the leftmost agent initialized with a mean position of $x = 40$, this spacing allows for an approximately symmetric distribution of cells around the center of the domain (on average). In order to update the ILM we again use a random sequential update algorithm. In each time step of length $\tau$, $N$ agents are chosen to attempt to move. Moves are attempted with “movement probability” $P^m$. A movement event consists of an agent centered at position $x$ attempting to jump to $x \pm \Delta$. If the chosen movement would cause the moving agent to overlap with another agent, we allow a push to occur with “pushing probability” $Q^n$, whereby the moving agent will displace the adjacent agent far enough for it to move a distance $\Delta$. If this push is unsuccessful (with probability $1 - Q^n$) or the pushed cell would overlap another cell, then the movement is aborted. See Fig. 8 for the possible ways occupancy at position $x$ can change due to a single movement or pushing event.

A. Continuum model for average occupancy

We derive a PME in the same manner as for the on-lattice case by considering the probability density functions for the positions of the agents. Let $C_j(x,t)$ denote the probability density function for the position of the center of the $i$-th agent. Assuming independence of agent positions, the probability of the center of an agent $j$ (which is not agent $i$), $y_j$, occupying the region $[x + 2R,x + 2R + \Delta]$ is given by

$$\mathbb{P}(j \neq i : y_j(t) \in (x + 2R,x + 2R + \Delta)) = \sum_{j \neq i} \int_{2R}^{2R+\Delta} C_j(x+s,t)ds.$$ 

The PME then can be formulated by enumerating the possible changes in $C_j(x,t)$ as presented in Fig 8:

$$C_j(x,t + \tau) - C_j(x,t) = -\frac{P^m}{2} C_j(x,t) \left[ 1 - \sum_{j \neq i} \int_{-2R}^{-2R-\Delta} C_j(x+s,t)ds \right] + \left[ 1 - \sum_{j \neq i} \int_{2R}^{2R+\Delta} C_j(x+s,t)ds \right]$$

$$+ Q^n \sum_{j \neq i} \int_{-2R-\Delta}^{-2R} C_j(x+s,t) \left[ 1 - \sum_{j \neq i} \int_{-4R-\Delta}^{-4R} C_j(x+S,t)ds \right] ds$$

$$+ Q^n \sum_{j \neq i} \int_{2R}^{2R+\Delta} C_j(x+s,t) \left[ 1 - \sum_{j \neq i} \int_{2R+\Delta}^{4R} C_j(x+S,t)ds \right] ds$$

$$+ Q^n \sum_{j \neq i} \int_{-2R-\Delta}^{-2R} C_j(x+s,t) \left[ 1 - \sum_{j \neq i} \int_{-4R+\Delta}^{-4R} C_j(x+S,t)ds \right] ds$$

$$+ Q^n \sum_{j \neq i} \int_{2R}^{2R+\Delta} C_j(x+s,t) \left[ 1 - \sum_{j \neq i} \int_{2R+\Delta}^{4R+\Delta} C_j(x+S,t)ds \right] ds$$

$$+ \frac{P^m}{2} C_j(x-\Delta,t) \left[ 1 - \sum_{j \neq i} \int_{2R-\Delta}^{-2R} C_j(x+S,t)ds \right]$$

$$+ \frac{P^m}{2} C_j(x+\Delta,t) \left[ 1 - \sum_{j \neq i} \int_{-2R}^{-2R+\Delta} C_j(x+S,t)ds \right]$$

$$+ \frac{P^m Q^n}{2} C_j(x-\Delta,t) \sum_{j \neq i} \int_{2R-\Delta}^{2R} C_j(x+S,t) \left[ 1 - \sum_{j \neq i} \int_{s+2R}^{4R} C_j(x+S,t)ds \right] ds$$

$$+ \frac{P^m Q^n}{2} C_j(x+\Delta,t) \sum_{j \neq i} \int_{-2R-\Delta}^{-2R} C_j(x+S,t) \left[ 1 - \sum_{j \neq i} \int_{s-2R}^{-4R} C_j(x+S,t)ds \right] ds$$

$^4$In the referenced excluded-volume models, particles can interact and, hence, in some senses, displace each other. However, we emphasize that in our model by “push” we mean a specific form of targeted displacement in which a cell actively displaces another cell for the purpose of moving or proliferating into the resulting free space.
+ \sum_{j \neq i} \frac{P^n Q^m}{2} C_j(x - 2R - \Delta, t) \int_{-\Delta}^{0} C_i(x + s, t) \left(1 - \sum_{j \neq i} \int_{s+2R}^{2R} C_j(x + s + t)dS\right)ds \\
+ \sum_{j \neq i} \frac{P^n Q^m}{2} C_j(x + 2R + \Delta, t) \int_{0}^{\Delta} C_i(x + s, t) \left(1 - \sum_{j \neq i} \int_{s-2R}^{-s} C_j(x + s + t)dS\right)ds. \quad (9)

Each of the 12 lines in the PME refers to one of the panels of Fig. 8 or its leftward-moving counterpart (not shown).

We can Taylor expand these terms in $s$, in the same way, to obtain a PME free of integrals. Ignoring terms of $O(R^4 \Delta^m)$ for $n + m \geq 4$ leads to the following PDE for the evolution of the probability density function of agent $i$ (after rearranging, dividing by $\tau$ and taking the usual diffusive limit):

$$
\frac{\partial C_i}{\partial t} = D \frac{\partial^2 C_i}{\partial x^2} + 2DR(2 - Q^m) \frac{\partial}{\partial x} \left( C_i \sum_{j \neq i} \frac{\partial C_j}{\partial x} \right), \quad (10)
$$

where, in analogy with Eq. (4),

$$
D = \lim_{\tau, \Delta \to 0} \frac{P^n \Delta^2}{2\tau}. \quad (11)
$$

This equation for the evolution of the probability density of agent $i$ is not closed, since it contains the expressions for the density of all the other agents, $C_{j \neq i}$. However, if all agent positions are initially chosen from the same distribution, then $C_i(x, t) = C_j(x, t) \forall i, j$, so $\sum_{j \neq i} \partial C_j/\partial x = (N-1)\partial C_i/\partial x$. Defining the total density to be $C(x, t) = \sum_{i=1}^{N} C_i(x, t) = NC_i(x, t)$ and summing Eq. (10) over $i$, yields

$$
\frac{\partial C}{\partial t} = D \frac{\partial}{\partial x} \left( \left(1 + 2R(2 - Q^m) - \frac{N-1}{N} C\right)\partial C \partial x \right). \quad (12)
$$

It is of comfort to note that upon setting the pushing probability, $Q^m$, equal to zero we return to the PDE for off-lattice volume-excluding agent movement derived by Dyson et al. [22].

In order to ascertain how closely our PLM represents the average behavior of the agents in the ILM we compare the evolution of agent density in each model. To facilitate this comparison each agent in the ILM is represented by a Gaussian kernel density function centered on its position. An average density profile is calculated by summing these Gaussians in each realization and then averaging the resulting profile over each of the repeats. In particular, we have found that Gaussian kernels of unit bandwidth give a smooth averaged solution. These averaged and smoothed individual-level density profiles are compared directly to the numerical solution of Eq. (12) in Fig. 9. We see qualitatively that the agreement between the PDE and the averaged individual density is very good in the case of little or no pushing [Figs. 9(a) and 9(b), respectively]. However, when pushing increases the correspondence begins to break down [see Figs. 9(c) and 9(d)]. In particular, the PDE overestimates the average density of the ILM in the center of the domain where density is high and underestimates the density when the density is lower.

Previously Dyson et al. [22] and Dyson and Baker [23] have noted that agent radius, $R$, and distance moved, $\Delta$, are key parameters resulting in changes to the diffusion coefficient. This remains true in the PDEs we derive for pushing. In particular, in Fig. 9 we do not see a distinctive change in the behavior of the solution of the PDE as we increase the pushing probability $Q^m$. In part this can be explained by the particular choice of parameters. For our relatively small choice of $R$, volume exclusion does not change the PDE significantly from the diffusion equation. Since pushing occurs through the volume exclusion mechanism its effects on the PDE are also limited by the magnitude of $R$.

The evolution of the HDEs between the ILM and the PLM are shown in Fig. 10. The results corroborate our qualitative conclusions from the density comparison plots. The quality of the correspondence between the two models decreases as the probability of pushing increases. We postulate that this is due, at least in part, to the breakdown of our initial independence assumption with the increased propensity to push. In the off-lattice model pushing events tend to bring agents that were not previously touching into contact with each other. As such it may lead to aggregation of agents; a phenomenon which clearly breaks the independence assumption.

This “clumping” phenomenon may also help to explain the particular functional form of the PDE we derive from the off-lattice ILM. The augmented diffusion coefficient has the extra density-dependent term $-2RQ^m(N-1)C/N$ in comparison to the nonpushing case. Since this term is negative, particle spreading is retarded in comparison with the nonpushing case, consistent with the idea that pushing events in the off-lattice ILM tend to gather agents together rather than disperse them. This is in stark contrast to the PDE derived from the on-lattice ILM in which pushing only serves to increase the diffusion coefficient.

FIG. 9. (Color online) A comparison of the averaged and smoothed agent density in the one-dimensional ILM with $N = 20$ cells and the corresponding PDE (12) for a range of values of the pushing probability $Q_m$. The profiles are visualized at times $t = 50$, $t = 100$, and $t = 200$. The comparison between the PDE and the ILM reduces in quality as we increase the pushing probability, $Q_m$. Parameters for these simulations were chosen as $R = 0.17$, $d = 0.1$, $\tau = 0.04$, $P_m = 1$. In each ILM simulation agents are initialized quasirandomly in the region $[35, 65]$ so no agents overlap with each other. The initial condition for the PDE is taken to be the average initial condition in the ILM. Movements which would cause an agent to leave the domain are aborted. All individual-level results are averaged over 10,000 repeats.

V. DISCUSSION

We have introduced a variety of on-lattice ILMs in which agent-agent pushing is explicitly incorporated and have attempted to discern how the macroscale behavior of models with pushing differ from their nonpushing counterparts. One quantitative way to do this is to derive the corresponding mean-field PLM and consider the solution of the PDE for different values of the pushing parameter. In each of the on-lattice cases we considered, pushing was found to augment both the diffusion coefficient and the source term (due to proliferation), in broad agreement with our findings when simulating the ILM. This result is in broad agreement with the finding of Bruna and Chapman [27] that an enhanced collective diffusion rate results from explicitly incorporating hard-core excluded-volume effects (which effectively allow particles to interact with or “push” each other).

Upon incorporating more complicated pushing mechanisms such as the linear pushing of multiple agents (rather than just a single agent) we found that the independence assumption used to derive the PLM begins to break down as correlations are introduced into the ILM.
We also derived a continuum PDE from an off-lattice ILM that incorporates agent-agent pushing. Interestingly, we found that, for the off-lattice model, pushing reduced the diffusion coefficient in the corresponding PDE. In part this may be an artifact of the way we have incorporated pushing into the off-lattice model. When one cell tries to move into a region already occupied by another, it may push the obstructing cell to complete its movement event but will remain touching the obstructing cell. The two cells that were not in contact when the movement event started are touching at the end of the movement event. As such, pushing, implemented in this manner, may lead to slower dispersal of agents corresponding to a reduced diffusion coefficient. There may be alternative off-lattice pushing mechanisms [in which pushing agents do not remain touching after a push, but rather momentum is transferred from one to the other (like billiard balls), for example] for which pushing serves to augment the diffusion coefficient, as in the on-lattice case. This serves to illustrate that it is important to accurately characterize individual cell behaviors precisely when modeling cell migration since inaccurate characterization can lead to the prediction of qualitatively different behavior in the resulting models.

Although we have attempted to investigate a range of different pushing mechanisms in this work, there are many questions about the modeling of cell-cell pushing which remain unaddressed. As intimated above, there are a variety of different ways to interpret cell-cell pushing in both on- and off-lattice models. Some of these mechanisms may lead to increased diffusion coefficients for the PLMs corresponding to the off-lattice model or, conversely, decreased diffusion coefficients for the PDEs corresponding to the on-lattice model. Investigation of a variety of biologically motivated pushing mechanisms and their corresponding continuum equivalents would, therefore, be an interesting line of exploration. In addition, attempting to derive the PDE from the off-lattice ILM in higher dimensions remain open challenges.

It is possible that cells that are pushed but have no room to move into may instigate pushes of their own in order to create space and, consequently, that the "second generation" pushed cell instigates pushes on a third generation and so on. Although we have implemented this idea for pushing in a straight line, it may be possible to incorporate such a "pushing cascade" for more complicated pushing mechanisms (such as the adjacent pushing mechanisms) into our ILMs. However, the increased complexity of this situation may mean that, even if it is feasible to derive the corresponding continuum equation, the correlations introduced by this "higher-order" pushing may render the continuum approximation a poor representation of the ILMs. In order to address this problem, and, indeed, we presented the worsening correspondence between the ILM and PLM in the linear pushing model in Sec. III B as $K$ increases, we could consider using higher-order moment closure schemes (rather than the simple independence assumption) [41–44] or correlation functions which explicitly account for two- (or more) point distribution functions [34,35]. Although there remains a great deal to investigate, in this work we have taken the first steps towards understanding the effects of cell-cell pushing on the macroscale migration of groups of cells. Our results have highlighted that the incorporation of pushing can be important for cell dispersal, producing qualitative changes in the corresponding macroscale PDE. However, the explicit incorporation of pushing into the ILM must be done carefully in order to capture the specific biological pushing mechanism, since different interpretations of pushing can lead to significantly different outcomes at the population level.
