Conservative Tibial Resection and Vertical Cut
Minimise Risk of Tibial Plateau Fracture after UKR

Introduction
Tibial fracture is a known complication after unicompartamental knee replacement (UKR) [1]. The clinical consequences of tibial fracture can be severe. Unless the fracture occurs and propagates intraoperatively, further surgery is usually necessary and in severe cases revision to a stemmed total knee replacement may be required.

Our aim was to identify surgical factors that contribute to fracture. We examined the influence of tibial saw cuts on the risk of fracture after cementless UKR, to determine if changes in tibial preparation could minimise the risk of fracture.

Results and Discussion
Some of the finite element models, particularly those with a deep posterior vertical cut, had a region at high risk of fracture which followed a line from the vertical cut to the cortex (Fig. 3) which is a typical path of fracture observed in clinically [1]. The generalised linear regression model found that both the resection depth and the depth of the vertical cut posteriorly significantly increased the risk of fracture (Fig. 4, and Table 1).

Furthermore, the regression model showed that an excessively deep horizontal cut, both posteriorly and anteriorly, reduced the risk of fracture. Although significant, the positive influence of an excessive horizontal cut was not as great as the negative influence of an excessive vertical cut or resection depth.

The overall regression fit had a correlation coefficient of 0.77 indicating the parameters assessed accounted for the 77% of the variation.

Methodology
Twenty three tibial Sawbones from an instructional course were measured to identify the typical surgical cut positions and depths for unicompartamental knee replacement. Parameters measured are shown in figure 2. The distributions for each parameter were found and these were then used to create the finite element models.

Using the Monte Carlo method, a thousand finite element models were created using Abaqus software (version 6.12, Simulia, Providence, RI) each one with a different combination of surgical cuts. The process was automated using python scripting.

The risk of fracture (ROF) was quantified using the definition reported by Schileo et al. based upon the principal strain ($\epsilon$) criterion, where:

$$\text{ROF} = \begin{cases} \frac{\epsilon}{0.0073} & \text{if tensile} \\ \frac{\epsilon}{0.0104} & \text{if compressive} \end{cases}$$

The models were based upon a study performed previously [2]; material properties of the bone were assigned using the Hounsfield units of the CT scan, the distal end of the tibia was fixed in all degrees of freedom and the loads applied were found from a musculoskeletal model based upon measurements from an instrumented knee prosthesis. A mesh size of 2.4 mm was used after performing a mesh convergence study.

A generalised linear regression model was performed to examine each parameter and how it influences the risk of fracture, using R (www.r-project.org).

Conclusions
The results of this study have highlighted the importance of careful surgical preparation of the tibial plateau prior to UKR implantation. This study suggests that the cause of fracture is multifactorial, and that to minimise the risk of fracture a surgeon should: (1) ensure that the vertical cut does not go too deep posteriorly, and (2) be conservative with resection of the tibia.

Instrumentation may play a role in achieving these goals. If the horizontal cut were to be made prior to the vertical cut, a shim could be inserted to stop the vertical cut from going too deep. This would increase the chance of the horizontal cut being extended further laterally underneath the tibial spines and present a deep vertical cut, both of which decrease the risk of fracture. Improvements could also be made to surgeon training and the risk could be better communicated.
