ABSTRACT: Lead halide perovskites have rapidly emerged as candidate materials for high-performing solar cells, but show serious issues related to long-term stability. Methylammonium (MA) lead perovskites with mixed iodide-bromide compositions, MAPb(I\(_x\)Br\(_{3-x}\)), are reported to exhibit improved stability, but the origin of such behaviour is not fully understood. Here, we report new insights into the degradation properties of MAPb(I\(_x\)Br\(_{3-x}\)) using ab initio simulations and a range of spectroscopic techniques. Absorbance spectroscopy shows that as the Br content increases the material stability towards oxygen and light increases. Isothermal gravimetric analysis and time-resolved single photon counting show that the amount of oxygen incorporation into perovskite films decreases significantly with increasing Br content. Ab initio simulations indicate that the degradation reaction involving superoxide species is energetically exothermic for pure MAPbI\(_3\), but becomes less favourable with increasing Br content with an endothermic energy for pure MAPbBr\(_3\). The simulations indicate shorter N-H...Br hydrogen bonds between the MA\(^+\) cation and Br ions, which would promote greater structural stability upon bromide substitution. Thin-film passivation with iodide salts is shown to enhance the stabilities of mixed-halide perovskite films and solar cell devices. The greater fundamental understanding of mixed iodide-bromide systems gained from this study is important for the future design of stable perovskite solar cells.

• Introduction

Hybrid lead halide perovskites have been generating enormous interest over the past few years for use in low cost and soluble - processable solar cells as well the recent avenue of perovskite-silicon tandem cells.\(^1\)-\(^1\)\(^8\) Of particular interest has been methylammonium lead iodide (MAPbI\(_3\)), which has demonstrated promising results in terms of photovoltaic performance in a wide range of device architectures.\(^1\)-\(^4\) However, an important issue regarding its commercial application is their long-term material stability under ambient operating conditions.

There are a number of factors that affect the degradation of perovskite solar cells, namely, moisture, temperature and UV illumination.\(^19\)-\(^31\) In previous studies,\(^32\)-\(^34\) we have demonstrated that when MAPbI\(_3\) is exposed to oxygen and light, a photodegradation process occurs via the formation of a superoxide species. From these initial findings, a technique to passivate vacancy defects was reported, involving post treatment with an iodide salt, resulting in enhanced film and device stability.\(^32\)

Recent studies have observed that anion substitution (bromide for iodide) to create mixed-halide perovskite films generates longer operational lifetimes and high power conversion efficiencies.\(^35\)-\(^42\) In particular, MAPb(I\(_x\)Br\(_{3-x}\)) has been reported to show enhanced stability towards ambient conditions and increased moisture tolerance when the bromide content is increased\(^,\(^35\)-\(^43\)\(^-\(^50\) although for intermediate compositions (x = 0.5), there are reports of halide segregation.\(^51\)-\(^57\) However, the origin of this stability behaviour is not fully understood and therefore remains unclear.

Herein, we investigate the mixed-halide system MAPb(I\(_x\)Br\(_{3-x}\)) with the overall aim of understanding the key factors behind the enhanced stability in such materials, using a range of computational and experimental techniques, such as UV/VIS, fluorescence, time-resolved phospho-
luminescence (TRPL), Transient absorption spectroscopy (TAS) and density functional theory (DFT) simulations. These techniques were selected as they have previously been shown to help identify the rate of degradation and the yield of superoxide along with the impact on charge separation going beyond our previous work.\(^32\)-\(^34\),\(^58\) We show that as the bromide content is increased the yield of superoxide decreases and consequently the material stability towards oxygen and light also increases. In addition, we investigate the energetics of degradation reactions and the role that iodide salt treatment can play in obtaining more stable mixed-halide perovskite films and solar cell devices.

• Results and discussion

Bromide substitution and superoxide yields. We first assess the stability of MAPb(I\(_x\)Br\(_{3-x}\)) perovskite films
deposited on glass substrates towards dry air (oxygen) and light, by employing UV/VIS spectroscopy to monitor the degradation. The method used is in accordance with our previous work, where a selected wavelength is used to monitor the transformation from the starting material to the degradation products.\textsuperscript{2,3} This is possible as the degradation mechanism results in a colour change from the dark perovskite phase to a yellow lead iodide phase. Samples with a range of values from $x = 0.0$ to $1.0$, were selected to explore the impact of bromide substitution on stability towards the degradation conditions. The absorption spectra of the mixed halide perovskite samples studied are shown in Figure 1a.

We now consider the effect of light and oxygen on the stability of MAPb(I$_{1-x}$Br$_x$)$_3$ perovskite films. The UV-vis absorption spectroscopy measurements presented in Figure 1b highlight that in all cases where iodide is present degradation occurs. Importantly, the time taken for the perovskite sample to degrade increases with increasing bromide content. To emphasize this, the pristine MAPbI$_3$ film ($x = 0$) completely degrades within 100 hours, whilst at $x = 0.75$, degradation takes over 400 hours. Furthermore, when no iodide is present, minimal observable degradation is seen over the experimental time frame. These observations suggest that film stability can be enhanced by bromide substitution and this has important implications for enhanced stability of solar cell devices.

The mechanisms behind the enhanced stability of MAPbBr$_3$ to light and oxygen may be attributed to a number of factors: the generation of superoxide species, the thermodynamics of the degradation process, and the differences in oxygen incorporation into the film. First, to probe the effect of superoxide generation as a function of bromide content we measure the yield of photoinduced superoxide. Figure 1c, shows the superoxide yields measured for the same film compositions explored in Figure 1a. The data collected shows that increasing the bromide content reduces superoxide yields.

Next, we seek to understand how the role of oxygen diffusion into films may be impacted by bromide substitution and this can also account for the enhanced stability reported in Figure 1. To investigate this, we used a combination of isothermal gravimetric analysis (IGA)\textsuperscript{32} and photoluminescence spectroscopy. In the IGA experiment, samples were prepared and sealed in an inert atmosphere, and then the weight increase was measured as a function of time under oxygen flux into the chamber. The data presented in Figure 2a and Table S1 of the supporting information shows an inverse correlation between bromide content and oxygen incorporation into the film. It appears that exchanging iodide for bromide leads to less oxygen stored within films, which can, in part account for the reduced superoxide yields observed for higher substitution levels.

To further probe this effect we used photoluminescence (PL) spectroscopy, which gives us a depth-selective probe of oxygen ingress. By exciting the perovskite at a wavelength of 404nm, at which the penetration depth of light is estimated to be 10nm, we are able to obtain specific PL information from the desired face of the perovskite film.\textsuperscript{59} Moreover, the interaction between O$_2$ and MAPbX$_3$ is known to increase the PL signal on account of a passivation effect.\textsuperscript{50,55} Therefore, by probing the PL signal from the substrate of the sample (furthest from the air interface) as a function of time in

Figure 1. Raw absorbance spectra for pristine films before degradation; b) Normalised absorbance decays as a function of aging under oxygen and light conditions for MAPb(I$_{1-x}$Br$_x$)$_3$ where $x = 0, 0.1, 0.2, 0.5, 0.75$ and 1. Films become more stable as the bromine content increases; c) Superoxide yield generation (raw data, as collected) for the same film compositions. Superoxide yields decrease as the bromide content increases. Note, that the data shown in Figure 1c) is presented in the form: superoxide yield (normalized for photons absorbed) versus time in our previous work by Pont et al.\textsuperscript{35}
O₂ we can ascertain how easily O₂ propagates through the films. In light of this, Figure 2b shows that oxygen is incorporated into MAPbI₃ films, as evidenced by the rapid increase in PL. It is also evident that when a higher content of Br is present in the films, this effect is subdued. In fact, no increase in PL is observed in the case of MAPbBr₃. It is important to note that when the MAPbBr₃ was probed at the surface (Figure S1) there was a significant increase in PL. This data implies that oxygen is present at the surface of the MAPbBr₃ film but is blocked from entering the interior of the sample.

**Degradation reaction energetics and structural effects.** To complement the experimental work, *ab initio* simulation techniques were used to investigate the effects of bromide substitution on the degradation process, building on our previous successful computational studies.⁴²-⁶⁴ We first explored the degradation pathway leading to water and lead halide formation in the presence of oxygen:

\[
4\text{CH}_3\text{NH}_3\text{PbX}_3 + \text{O}_2 \\
\rightarrow 4\text{PbX}_2 + 2\text{X}_2 + 2\text{H}_2\text{O} + 4\text{CH}_3\text{NH}_2
\]  

where an O₂ molecule is introduced onto the same I vacancy site in all compositions apart from the pure Br composition, in which the site is a Br vacancy.

Figure 3 shows the reaction energies as a function of Br content in MAPb(IₓBrₙ₋ₓ)₃ with full data given in Table S2. For MAPbI₃ the energy of reaction (1) is calculated to be 1.56 eV per oxygen molecule, indicating that the degradation process in the absence of light is unfavourable, which is consistent with observation and previous work.⁴² In addition, the energy for this degradation reaction (1) for MAPbBr₃ is even more unfavourable, with a calculated value of 4.98 eV, which points to the enhanced stability of this perovskite. In our analysis, we use the configuration with the highest probability of occurrence at 300 K in the mixed systems, with the number of equivalent and inequivalent configurations given in Table S3. We are now able to calculate the average lattice parameters as a function of composition (Figure S2), as well as the energy of mixing (Figure S3). Our results suggest complete mixing of Br and I, which are stabilised by entropic effects. We note there has been debate concerning mixed-halide phase segregation especially in the MAPb(I₀.₅Br₀.₅)₃ composition.⁵¹

As suggested in recent work,⁴⁰ we also investigated the degradation pathway where O₂ acts as a catalyst, degrading methylammonium ions into methylamine and hydrogen. We find this reaction to be ~5 eV higher in energy than degradation through water formation, indicating that the process is much less favourable, and suggests that O₂ does not act as a catalyst.

For degradation to occur the film must be exposed to O₂ and light. Under illumination O₂ acts as an electron scavenger absorbing photoexcited electrons. The next step would be for superoxide to react with the positively charged photo-oxidized perovskite, indicated by * in the following equation:

![Figure 2.](image)

**Figure 2.** a) Oxygen ingress in CH₃NH₃Pb(IₓBrₙ₋ₓ)₃ films. a) Isothermal Gravimetric Analysis (IGA) traces of CH₃NH₃Pb(IₓBrₙ₋ₓ)₃ films after exposure to dry air flux. b) Normalized photoluminescence intensity obtained from samples pumped with a 404 nm laser incident on the substrate face of the perovskite. The increase of this intensity is shown over time after exposure to ambient air in the dark.
Degradation of MAPbI$_3$ is now found to be favourable, with a reaction energy of -1.39 eV per superoxide ion. In contrast, for MAPbBr$_3$ the degradation reaction is found to be unfavourable with an endothermic reaction energy of 2.00 eV (Figure 3). This is consistent with our experimental results that show O$_2$ / light degradation of MAPbI$_3$ and enhanced stability of MAPbBr$_3$ (Figure 1c). For comparison we also show the calculated reaction energies for the mixed-anion phases MAPb(I$_x$Br$_{1-x}$)$_3$, indicating that the degradation reaction in the presence of superoxide becomes less favourable with increasing Br content. This directly supports our experimental results of enhanced film stability with increasing bromide content. In the mixed systems we find the lowest degradation pathway leads to the formation of PbBr$_2$ and I$_2$. We note that previous calculations$^{40}$ on the phase diagram for MAPb(I$_x$Br$_{1-x}$)$_3$ reveal a thermodynamic metastability for intermediate I/Br compositions.

Other factors that could also contribute to the stability of MAPbBr$_3$ are a change in the hydrogen-bonding between the methylammonium cation and the anion lattice, or a decrease in optical absorbance of the perovskite. Comparing the end members MAPbI$_3$ and MAPbBr$_3$, in which there is complete substitution of iodide with the smaller bromide ion, the calculated cell-volume is reduced by 15.8%, which is in agreement with experimentally reported values of up to 17% (Figure S2).$^{65,66}$ XRD diffraction gives Pb-I and Pb-Br bond lengths of 3.16 and 2.97 Å respectively. These values are in line with our calculated bond lengths of 3.21 and 3.00 Å, suggesting stronger Pb-Br bonds that need to be broken in the degradation process. Our DFT simulations indicate that this contraction also leads to shorter H-bond distances between the NH$_3$ groups and Br ions, as shown in Figure 4. Consistent with our simulation results, XRD and Raman studies$^{41}$ find the shortest H-Br bond distance of 2.36 Å in the tetragonal phase (between about 140 and 230 K) and 2.46 Å in the cubic phase, above 230 K (Table S4). Such structural effects would result in stronger H-bonding in MAPbBr$_3$ and hence impart greater structural stability. We also find that the H-X distance between the CH$_3$ group and the Br are greater than 3 Å showing they do not form H-bonds, which is in agreement with Yin et al. who report that CH$_3$-Br hydrogen bonds only form in the orthorhombic phase of MAPbBr$_3$.$^{31}$

The contraction of the perovskite lattice also suggests an additional factor in the enhanced stability of Br-containing samples through the restriction of O$_2$ diffusion through the film.

This is further supported by scanning electron microscope images reported by Atourki et al. who show that in contrast to MAPbI$_3$ thin films which form fibre-like crystals with voids between them, MAPbBr$_3$ form larger aggregate crystals, which would further limit diffusion.$^{65}$ Indeed, the combination of the findings in this section and Figure 2 suggests that O$_2$ is less able to penetrate the interior of Br-rich films on account of the smaller unit cell providing a physical barrier to O$_2$ diffusion. Interestingly, such structural contraction in MAPbBr$_3$ would also inhibit MA$^+$ migration in comparison to MAPbI$_3$, which warrants further investigation.

**Film passivation via salt treatments.** The enhanced stability of mixed-halide perovskites makes them more desirable for solar cell applications. However, as the bromide content increases the optical properties become less favourable for efficient photovoltaic devices. For example, the absorbance data (Figure 1a) shows that upon increasing the bromide content, the band edge shifts and there is less absorption at higher wavelengths, which translates to less efficient solar cell devices. Consequently, we now consider if we can further enhance the stability of the mixed-halide perovskites by surface passivation via iodide salt treatments.$^{35}$ Of particular interest are the lower bromide content films as they allow the stability to be optimized whilst maximizing the spectral characteristics for light harvesting.

$$\text{4CH}_3\text{NH}_3\text{PbX}_3 + \text{O}_2 \rightarrow \text{4PbX}_2 + 2\text{X}_2 + 2\text{H}_2\text{O}$$

$^{(2)}$
In these experiments, we employed methylammonium iodide (MAI) as a coating agent with concentrations of 0.01M, 0.005M and 0.001M and then applied them to films with bromide content of \(x = 0.2\), \(x = 0.5\) and \(x = 0.75\). UV/VIS was used to track the degradation towards oxygen and light at a selected wavelength (700 nm for \(x = 0.2\), 600 nm for \(x = 0.5\) and 550 nm for \(x = 0.75\)) and the data normalized with respect to the fresh sample of each film and coating combination. The results obtained from this study are presented in Figure 5, which shows a plot of the absorption as a func-

**Figure 5.** Application of MAI salt coatings (0.01M, 0.005M and 0.001M) to the mixed halide perovskite system MAPb(I\(_1-x\)Br\(_x\))\(_3\) with compositions of a) \(x = 0.2\), b) \(x = 0.5\) and c) \(x = 0.75\) and the impact on the normalised absorbance decay with exposure to the degradation conditions. As bromide content increases the salt concentration required to increase stability decreases.

with bromide content of \(x = 0.2\), \(x = 0.5\) and \(x = 0.75\). UV/VIS was used to track the degradation towards oxygen and light at a selected wavelength (700 nm for \(x = 0.2\), 600 nm for \(x = 0.5\) and 550 nm for \(x = 0.75\)) and the data normalized with

**Figure 6.** Superoxide generation yields for film compositions of a) \(x = 0.2\), b) \(x = 0.5\) and c) \(x = 0.75\) in MAPb(I\(_1-x\)Br\(_x\))\(_3\) as a function of MAI salt coating (0.01M, 0.005M and 0.001M). Increasing bromide content reduces the salt concentration required to reduce the yields of superoxide).
example, the tolerance of the perovskite film to oxygen and light progressively increases as the concentration of the MAI salt solution is increased. For the highest concentration applied (0.01M) all films exhibit enhanced lifetime, where little to no observable degradation occurs over the time frame examined. This implies that using this salt concentration enables passivation of iodide vacancies in the film.

To investigate whether the increased stability of the films as a result of the salt treatments is due to the passivation of vacancy defects and reduced superoxide generation, the superoxide yield was determined for the samples presented in Figure 6. The results of this study shows that for all Br-containing compositions, increasing the salt treatment concentration leads to reduced superoxide yields. Taken together, the data presented in Figures 5 and 6 shows that the perovskites with a higher bromide fraction can be stabilized with a lower concentration of MAI salt treatment. Additionally, as a control, we examined the impact of using methylammonium bromide (MABr) as a stabilizing treatment, which showed no improvement in increasing film stability or in reducing the yield of superoxide. Both MAPbI₃ and MAPbBr₃ were coated with a 0.01M concentration of MABr and the results of these experiments are shown in Figure S5.

To gain further insight into the role of bromide substitution and the impact of film passivation with the MAI salt, time-resolved photoluminescence (TRPL) was employed. Iodide vacancies provide a source for non-radiative recombination, and so when the perovskite film is passivated, the photoluminescence lifetime is expected to increase. Figure S6, shows the TRPL data obtained for a range of 4 samples with a composition of x = 0, 0.1, 0.2, 0.5, and with and without a MAI coating of 0.01M. As can be seen, passivation of the films with the iodide salt leads to an increase in PL lifetime.

Implications for device performance. We now consider the effect of bromide substitution on the yield of photoinduced charge separation to the perovskite hole
transport material heterojunctions upon exposure to oxygen and light. The rate of charge separation losses have been shown to be directly related to the decay of device performance in operating perovskite solar cells. The yield of hole transfer from the perovskite to the hole-transporting phase, Spiro-OMeTAD, is measured using transient absorption spectroscopy as described in the experimental section. Films with compositions of \( x = 0, 0.2, 0.5, 0.75 \) and 1, are examined in an architecture of glass/mp-Al:O/ MAPb(1-x,Br)\(_3\)/Spiro-OMeTAD and probed at 1600 nm (tracking concentration of Spiro-OMeTAD hole polarons) following excitation at 458 nm. The change in optical density (\( \Delta OD \)) value at 1 \( \mu \)s was obtained and then normalised against the starting value, where the sample has not been exposed to the degradation conditions. The films were exposed to dry air flux and ambient illumination. Measurements were recorded at regular time intervals over the course of an hour and under an inert nitrogen atmosphere.

Figure 7a presents the relationship between \( \Delta OD \) and time after being exposed to light and oxygen. It is clear that charge separation in the Br-rich films is well maintained even after exposure to light and oxygen. In fact, close correlation is found between the stability of the film, and its Br content. For example, for the fully substituted composition (100% Br) the impact on charge separation yield and therefore degradation is minimal, whilst in the I-rich perovskites, charge losses are significant within the timeframe explored. The time taken for the decay to drop to 50% of its original value is found to be 10, 15, 40 and 60+ minutes for the films \( x = 0, 0.2, 0.5 \) and 0.75, respectively. This further demonstrates that Br substitution enhances stability to oxygen and light, allowing films to retain optimum optoelectronic properties for longer periods of time.

We next turn our attention to the effect of iodide salt treatment on the yield of charge separation. To this end, we probed the mixed-halide perovskite films with transient absorption spectroscopy after treating them with 0.01M MAI salt solution. Figure 7b, shows the \( \Delta OD \) as a function of time for the 50% Br composition, with and without a salt coating before and after 60 minutes of exposure to dry air flux and illumination. We note that the decay traces presented in Figure 7b are indicative of recombination of electrons (or holes) in the perovskite with holes (or electrons) in the transport layers. Moreover, the data in Figure 7b shows that the uncoated film undergoes degradation, where the initial amplitude of the signal (\( \Delta OD \)) decreases significantly after an hour of exposure to light and oxygen. In contrast, no such drop in initial amplitude of the signal is seen in the film passivated with the MAI salt solution. Figure 7c presents the relationship between \( \Delta OD \) (at 1\( \mu \)s) and aging time for perovskite films of \( x = 0, 0.2, 0.5 \) and 0.75, with and without a 0.01M salt coating. Note, that all raw TAS traces are provided in Figure S7. It is clear from the data presented in Figure 7c that film passivation via MAI salt solutions generates more stable films that retain their initial charge generation capabilities.

Finally, we consider the effect of film passivation via MAI salts on the stability of mixed-halide perovskite solar cell devices. Devices comprised of the 20% bromide composition perovskite were fabricated and treated with MAI salt solutions of 0, 0.01M, 0.05M and 0.01M to generate four devices. The power conversion efficiency (PCE) of these devices was monitored as a function of exposure to oxygen and light and the normalized PCE as a function of time is plotted in Figure 7d. We note that the current – voltage curves collected under AM1.5 simulated light and are presented in Figure S8 and Table S5. The data presented in Figure 7d confirms that mixed-halide devices can be stabilized by the application of the salt coating. In addition, increasing the concentration of the salt coating progressively increases the stability of the solar cells.

### Conclusions

Our combined experimental-computational study using ab initio simulation and spectroscopy techniques improves our fundamental understanding of the degradation behaviour of mixed iodide-bromide perovskite solar cells and indicates design rules for enhancing their long-term stability. Our systematic investigation reveals the following key results:

a) Absorbance spectroscopy shows that as the Br content in the MAPb(1-x,Br)\(_3\) system is increased the material stability towards oxygen and light also increases, which correlates with the decreasing yield of superoxide species. Isothermal gravimetric analysis and time-resolved single photon counting show that as the Br content is increased the amount of oxygen incorporation into perovskite films decreases significantly. This partly accounts for the reduced superoxide yields observed for higher Br substitution levels.

b) Ab initio simulations on MAPb(1-x,Br)\(_3\) show that the degradation reaction involving superoxide species leading to water, lead halide and methylamine formation is energetically favourable and exothermic for pure MAPbI\(_3\), but becomes less favourable with increasing Br content. Indeed, for pure MAPbBr\(_3\) the degradation reaction is unfavourable and endothermic. This may be related to structural factors: the shorter and stronger N-H…Br hydrogen bonds found between the CH\(_3\)NH\(^+\) cation and Br ions would promote greater structural stability on bromide substitution.

c) Iodide salt treatment was employed to promote greater stability of perovskites. We find that thin-film passivation with MAI salts leads to enhanced stabilities of mixed-halide perovskite films and solar cell devices.

### Methods

**Materials.** All the chemicals were used as received, including 99% of PbI\(_2\) (Sigma-Aldrich), HI (57% in water, Sigma-Aldrich), PbBr\(_2\) (Sigma-Aldrich), MAI (Dyesol), MABr (Dyesol), Titanium diisoproxopide bis(acetylacetonate) 97%wt in isopropanol (IPA) (Aldrich), spiro-OMeTAD (Lumtec), Bis(triulfuromethane)-sulfonimide lithium salt (Li-TFSI, Aldrich), 4-tet-butylpyridine(TBP), acetone, ethanol, isopropanol, ethanolamine, 2-methoxyethanol, chlorobenzene, γ-butyrolactone (GBL), TiO\(_2\) paste (Dyesol DSL 30 NR-D 30nm), Terpineol, hydroethidine, tolune, Dime-thyl sulfoxide (DMSO), acetonitrile.
MAPbI$_3$ and MAPbBr$_3$ solutions and film fabrication. 0.25 g of MAI and 0.78 g PbI$_2$ were mixed in a 1:1 mole ratio in 1.4 ml of anhydrous GBL and 0.6 ml of DMSO for 1 hour at 60 °C. After that, they were left to precipitate overnight. The solution was filtered out with a 0.2 µm membrane in a small plastic tube. This solution was then pipetted into 2 consecutive spin steps under a nitrogen atmosphere in a glovebox. The first spin cycle was performed at 2,000 rpm, 2,000 rpm/s for 30 seconds followed by 4,000 rpm, 4,000 rpm/s for 30 seconds. During the second step, the substrate was treated with dry toluene (approximately 500ml) drop casting. The film was heated at 100 °C for 10 minutes. The colour of the films changed from yellow to black immediately after being placed on the hot plate. It is noted that it is entirely possible that while transporting and measuring, moisture started to corrode MAPbI$_3$ even though both samples are mostly degraded under a dry air environment. To minimise the amount of moisture getting into the films, the aged films were kept in a closed container with an excess of Si-drying agents underneath, before any characterization techniques were performed. MAPbBr$_3$ solutions and films were created using the exact same method as described above, except using the bromide derivatives, MABr and PbBr$_2$.

MAPb$_{(1-x)Br_x}$ film fabrication. Stock solutions of MAPbI$_3$ and CH$_3$NH$_3$PbBr$_3$ were prepared by dissolving stoichiometric ratios of PbX$_2$ and MAX$_3$ (X = I, Br) in a DMSO and GBL solution (7:3) at 1.25 M conc. and stirred for 60 minutes at 50 °C and room temperature, respectively. To obtain a range of composition in MAPb$_{(1-x)Br_x}$, stock solutions were combined in the desired volumetric ratios. Thin film samples were prepared on glass using an anti-solvent technique adapted from a previously reported method. Glass was washed in soap, acetone, and 2-propanol followed by a 10 min oxygen plasma treatment. The perovskite precursor solution was coated using a spin coating procedure using two speeds where toluene was dripped onto the surface during the second step and then dried at 100°C post deposition.

Spiro-OmeTAD. The HTM solution was prepared by dissolving 72 mg of spiro-OmeTAD in anhydrous 1 ml chlorobenzene solution. In case for device fabrication purposes, 32 µl of Li-TFSI precursor solution (175 mg of Li-TFSI powder in 1 ml of acetonitrile) and 10 µl of 4-tert-butylpyridine (TBP) is mixed with the Spiro-OmeTAD. The solution was then filtered with a 0.2 µm membrane in a small plastic tube. It was then spun at 4,000 rpm, 4,000 rpm/s for 40 seconds. For the TAS or UV-vis measurements, the films were measured immediately after the fabrication process.

Film coatings. Iodide salt solutions were prepared by dissolving the iodide salt (MAI or MABr) in a 1:4 solvent mixture of IPA to chlorobenzene. One hundred microlitres of this solution was then dripped onto pre-deposited perovskite films with a 20 sloading time before spinning at 4,000 rpm. and annealing at 100 °C for 5 min.

Aging conditions. Films were sealed in a controlled environment, where dry air was gassed through for the duration of the degradation and illumination was provided by a tungsten lamp equipped with a UV-blocking filter as previously reported.

Characterizations. UV-Vis measurements were carried out using a UV-Vis spectrometer (PerkinElmer) in the wavelength range from 400 to 900 nm with a scan speed of 480 nm per minute with 1 nm data intervals and cycle times of 1 second. Its slit width was 1.0 nm. TAS measurements were performed with a 567 nm dye and a GL-301 dye laser (Photon Technology International, TSI) through an oscilloscope (TG330 Function generator with 3 MHz-Generator, 120 MHz counter/sweep). The frequency of the laser pulse was 4 Hz. The pulse was generated with a light source (Bentham IL 1 illuminator) and a voltage of approximately 12.3 V (Bentham 605). The signal size was filtered with a long pass filter monochromator (Thorlabs) and an optical shielding filter. Each reading was measured at 10 ms time scales for 64 averages for 10 times with a pulse power of 25 µJ/cm$^2$. The aged sample was illuminated against a tungsten halogen lamp (Thorlabs) with an approximate power of 20 mW/cm$^2$ with a 400 nm long pass optical filter throughout the experiments. Each sample was also purged with dry compressed air (≤ 2 ppm moisture) during the ageing conditions.

Superoxide probe testing was achieved by dissolving 10 ml of stock solution (31.7 µM) of the hydroethidine (HE) probe in 10 ml dry toluene. Sonication was used to facilitate miscibility. Perovskite films were submerged into this solution. Photoluminescence spectra were recorded with excitation wavelength of 520 nm and slit width of 10 nm on a Horiba Jobin-Yvon Fluorolog-3 spectrophotometer. The film was illuminated with visible light through a 400 nm long pass optical filter throughout the experiment. A tungsten halogen lamp provided illumination. The light intensity was approximately 1.5 mW/cm$^2$.

TAS measurements were performed with a 567 nm dye and a GL-301 dye laser through an oscilloscope (TG330 Function generator with 3 MHz-Generator, 120 MHz counter/sweep). The frequency of the laser pulse was 4 Hz and it was generated with a Bentham IL 1 illuminator and a voltage of approximately 12.3 V. The signal size was filtered with a long pass filter monochromator and an optical shielding filter. Each measurement was measured at 10 ms time scales for 64 averages for 10 times with a pulse power of 25 µJ/cm$^2$. Photoluminescence measurements were performed by placing perovskite samples on a Horiba Jobin-Yvon Fluorolog-3 spectrophotometer with same settings as the superoxide probe measurements.

Ab initio simulations. In order to accurately describe the disorder in the MAPb$_{(1-x)Br_x}$, a symmetry-adapted ensemble of configurations was used as implemented in the Site Occupancy Disorder (SOD) program. Geometric optimisations of the generated structures were performed using density functional theory (DFT) with the Vienna Ab initio Simulation Package (VASP). Electronic exchange and correlation were modelled with the Perdew-Burke-Ernzerhof (PBE) functional, with van der Waals (vdW) corrections via the Tkatchenko-Scheffler electrodynamic screening method. A high kinetic energy cutoff of 520 eV was used. Geometry optimisations were performed on the
48-atom tetragonal unit cell, and a Γ-centred grid of \(4 \times 4 \times 3\) \(k\)-points was employed for Brillouin-zone integrations. The ionic positions were relaxed until the forces were less than 0.01 eV/Å on each atom. The configuration with the highest probability at 300 K was then investigated further using a \(2 \times 2 \times 1\) supercell (giving a tetragonal cell of 192 atoms) in the numeric atom-centred basis set all-electron code FHI-AIMS. \(^{7,4}\) Tight basis sets were used with tier 2 basis functions for all species using the PBE exchange-correlation functional and Tkachenko-Scheffler electronic screening scheme consistent with the geometry optimisations performed in VASP. Relativistic effects were considered using an atomic zeroth-order regular approximation (ZORA). \(^{74}\) A Γ-centred grid of \(2 \times 2 \times 3\) \(k\)-points was used for sampling, which was tested for convergence. O\(_2\) absorption was modelled at equatorial sites over apical sites as these were shown to be more favourable by 0.2 eV. To determine the spin state of the oxygen atoms we constrained the difference in the number of up- and down-spin electrons; corresponding to 0 for non-magnetic, 1 for the low spin state, and 2 \(\mu_B\) for the high spin state. Initial oxygen incorporation onto a vacancy site leads a low spin state (1 \(\mu_B\)), with photoexcitation shown to lead to a non-magnetic groundstate. Structures were relaxed with a convergence criterial of \(10^{-6}\) eV Å\(^{-1}\) for forces, \(10^{-6}\) eV Å\(^{-1}\) for electron density and \(10^{-5}\) eV for the total energy. The virtual-crystal approximation\(^{76}\) (VCA) was employed to model photoexcitation in the charged systems, this ensures the Fermi level does not change in the doped system. \(^{77}\) Using this method, we model the positively charged iodide vacancies by distributing the charge uniformly over the Pb atoms. The nuclear number of all the Pb atoms are reduced in the supercell by \(\Delta Z_{\text{Pb}} = -q/N_{\text{Pb}}\), where \(q\) is the charge of the iodide vacancy (+1) and \(N_{\text{Pb}}\) is the number of Pb atoms in the supercell. This leads to the introduction of vacant states at the valence band maximum (VBM).
