This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Single-step synthesis of nanostructured γ-alumina with solvent reusability to maximise yield and morphological purity

T. E. Bell, J.M. González-Carballo, R.P. Tooze and L. Torrente-Murciano

Insights of the chemical mechanism for the hydrothermal synthesis of nanostructured alumina are elucidated for the first time, demonstrating the effect of the NaOH : Al molar ratio not only on the resulting morphology of the material but also on the product yield. Highly uniform pure γ-Al₂O₃ nanorods are synthesised under acidic conditions (pH < 4), while basic medium (pH > 9) lead to γ-Al₂O₃ nanoplates. Maximisation of the morphological purity leads to a decrease in the overall aluminium yield which can be overcome by successful reusability of the synthesis medium in an effort to increase efficiency (yield and productivity) and minimise waste production towards feasible large-scale manufacturing of nanostructured materials.
production towards the scale-up of this synthesis towards manufacturing.

Experimental

Synthesis of γ-alumina nanorods

Boehmite nanorods are synthesised by hydrothermal treatment based on a modified method previously reported. In a typical synthesis, 4.8 g of aluminium nitrate nonahydrate (Al(NO₃)₃·9H₂O) is dissolved in 20 mL of deionised water before adding 10 mL NaOH solution of various concentrations. The combined 30 mL solution is transferred to a 45 mL Teflon lined stainless steel autoclave and treated hydrothermally for 20 hours at 200 ºC inside an air-circulating oven which allows uniform temperature to be achieved throughout the autoclave. After this time, the autoclave is allowed to cool to ambient temperature. The white powder obtained (γ-AlOOH) is separated from the solution by centrifugation (4000 rpm, 20 minutes), washed several times with deionised water and dried overnight at 80 ºC under vacuum. Large particles of agglomerated, dry γ-AlOOH powder are broken in a mortar prior to further investigation. Finally, the γ-AlOOH powder is calcined at 500ºC for three hours (3ºC/min heating rate) to yield γ-Al₂O₃.

In specific cases, the synthesis solution separated from the γ-AlOOH solid product by centrifugation is recycled in consecutive synthesis prior to addition of the corresponding amount of reactants (NaOH and Al(NO₃)₃·9H₂O), following the procedure described above.

Characterisation of γ-alumina nanostructured materials

Transmission electron microscopy (TEM) was carried out using a JEOL JEM1200EXII instrument. Energy-dispersive X-ray spectroscopy (EDX) was used to confirm the chemical composition of the sample with a Thermo Fisher Scientific NORAN System 7. N₂ adsorption measurements at -196 ºC were carried out using a Micromeritics ASAP 2020 apparatus. Specific surface area was calculated using the BET method and pore size distributions were calculated from the desorption data using the BJH model. Samples were degassed at 150 ºC prior to analysis in order to calculate specific surface area.

Thermogravimetric analyses (TGA) were carried out using a TGA-DTA 92 Type 31/1190, Setsoft 2000 instrument from 25 to 600ºC at a heating rate of 10ºC/min using nitrogen as a carrier gas. The phase identification of the samples was done by powder X-ray diffraction (XRD) analysis using a Bruker D8 Advance diffractometer and a position sensitive VANTEC-1 detector with Cu Kα radiation, operated at 40 kV and 40 mA.

Results and discussion

The study of the effect of the initial concentration of NaOH base during the hydrothermal synthesis of nanostructured boehmite (γ-AlOOH) in the absence of surfactant provides an insight into the chemical mechanism taking place during the synthesis. A systematic study of the synthesis of nanostructured boehmite by hydrothermal treatment at 200 ºC over 20 hours with different initial NaOH concentrations was carried out. Table 1 shows the different hydrothermal conditions including pH as well as the boehmite morphology obtained.

$^a$ Length : diameter ratio
$^b$ After calcination at 500ºC

An initial NaOH concentration of 1 M, results in the formation of well-defined regular 1D γ-AlOOH structures with average lengths of 260 nm and diameters of 27 nm. High morphological purity is obtained under these conditions, without the presence of other morphologies or amorphous materials as confirmed by TEM (Figure 1). Increasing the initial NaOH base concentration to 3.8 M during the synthesis results in a non-uniform combination of nanorods and a high proportion of 2D nanoplates of heterogeneous sizes. At higher NaOH base concentration values (5.9 M), a limited number of 1D structures are formed, with the majority of the product forming an irregular array of 2D nanoplates.

Figure 1 Effect of pH of the solution on the morphology of γ-Al₂O₃ (a, b, c) and γ-AlOOH (d, e, f) from hydrothermal synthesis (200ºC, 20h).

Figure 2 shows the differential of the thermogravimetric analyses for boehmite samples synthesised with 1 and 5.9 M NaOH, corresponding to nanorods and nanoplates respectively.
Both set of data are normalised per mass of material for easy comparison. The initial decrease in mass between 75 and 200 ºC corresponds to the removal of adsorbed and interstitial water. Prior to the analyses, the materials were dried at 80 ºC under vacuum, and consequently this removal of water suggests a hydroscopic boehmite nature. The loss of mass at high temperatures corresponds to the transformation of γ-AlOOH into γ-Al₂O₃, which takes place at a slightly lower temperature for the nanorods (460 ºC) compared with the nanoplates (507 ºC). Based on these results a temperature of 500 ºC is used for the calcination of boehmite, in agreement to the conditions used in the literature (between 300 and 500 ºC). The enthalpy change corresponding to the endothermic, isomorphous transformation is +8.98 kJ mol⁻¹ and +6.61 kJ mol⁻¹ for the nanorods and nanoplates respectively. Figure 1 shows representative TEM pictures of boehmite and alumina after calcinations, which confirm the literature expectations of a conservation of morphology after calcination. Interestingly, the lamellar structures stabilised at high base concentrations (5.9 M), under hydrothermal basic conditions, are stable at high temperatures.

The chemical transformations taking place during the boehmite synthesis is as follows; the dissolution of aluminium nitrate nonahydrate (Al(NO₃)₃·9H₂O) in an aqueous NaOH solution forms an initial white colloidal suspension of amorphous aluminium hydroxide (Al(OH)₃) according to Reaction (1). Al(OH)₃ is amphoteric and forms an equilibrium according to Reaction (2) depending on a delicate balance of the concentration of hydroxide ions which determines the prevalence of Al(OH)₃, the required precursor to γ-AlOOH and eventually γ-Al₂O₃. This equilibrium is also responsible of a variation of the pH of the solution before hydrothermal treatment. The pH values for each of the different concentrations of NaOH are shown in Table 1. At low concentrations of NaOH (< 5.9 M), the hydrothermal treatment takes place under acidic conditions. At the other end of the pH scale, basic hydrothermal conditions exist with the use of higher initial NaOH concentrations (> 5.9 M).

Under hydrothermal conditions, a lamellar γ-AlOOH product is formed according to Reaction (3). The final morphology of the resulting boehmite material strongly depends on the pH conditions during the synthesis. In acidic conditions, the presence of excess protons disrupts the hydrogen bonding between the layers allowing the lamellar boehmite structure to be separated into 2D layers which subsequently roll themselves to decrease their surface energy under a thermodynamic governed regime. Growth of the 1D structures, which determines the final aspect ratio of the nanostructures, follows the conventional dissolution-recrystallisation mechanism via Ostwald ripening, as previously reported for similar boehmite materials and other ceramic nanostructures, the rate of which is dictated by the specific synthesis conditions of each hydrothermal treatment.

The results herein determine that an increase of pH within the acidic regime results in a lower nanorods purity with the presence of nanoplates likely formed during the Ostwald ripening process involved in the growth of the rods. This observation does not agree with the results reported by Yang where an increase in morphological purity and crystallinity of the boehmite nanorods is observed upon increasing pH. The differences are likely to be due to variations in the experimental procedure (e.g. NaOH:Al ratio).

An excess of NaOH concentration results in basic hydrothermal conditions which stabilise the lamellar structures by hydroxylation of the under coordinated surface Al atoms to inhibit scrolling of the sheets to form 1D materials. Complete stabilisation of these lamellar structures is observed with an initial 5.9 M NaOH concentration, equivalent to a pH of 12.8 during the boehmite synthesis, as shown in Figure 1. These results confirm the key role of protons on the breakage of the hydrogen bonding network between the boehmite lamellar structure which leads to metastable layers as precursors for the rods as previously hypothesised by some authors.

The equilibrium in Reaction (2) also dictates the yield of boehmite product obtained as a function of the hydroxide ions initially present in the solution. Thus, the γ-Al₂O₃ yield (wt. %) is defined as: $\left(1 - \frac{m_{Al_{In}}}{m_{Al_{Out}}}\right) \times 100$, where $m_{Al_{In}}$ and $m_{Al_{Out}}$ correspond to the mass of aluminium in the precursor and product respectively.

This chemical mechanism is evidenced by the variations of alumina yield as a function of the molar ratio of reactants (NaOH : Al) shown in Reaction (1), irrespective of the resulting morphology. Specifically for this procedure, the stoichiometric
ratio of NaOH : Al(NO₃)₃·9H₂O in Reaction (1) corresponds to 
a initial NaOH concentration of 3.8 M, leading to the 
maximum yield of the boehmite hydrothermal product, 
approaching 100%. Figure 3 shows the relationship between 
alumina yield (wt. %) and the NaOH : Al(NO₃)₃·9H₂O molar 
ratio, where the error bars represent the amount of interstitial 
water in the product deduced by TGA analyses in Figure 2. It is 
important to note that variations on the initial amount of 
 aluminium precursor would consequently change this 
stoichiometric ratio. An increase of the NaOH : Al(NO₃)₃·9H₂O molar ratio above its stoichiometric value (< 3.8 M in this case) 
yields less boehmite product due to the lack of conversion of 
the aluminium precursor Al(NO₃)₃·9H₂O into Al(OH)₃ prior to 
the hydrothermal treatment. Conversely, an initial excess of 
NaOH concentration above the stoichiometric NaOH : 
Al(NO₃)₃·9H₂O molar ratio (> 3.8 M in this case) results in the 
dissolution of the Al(OH)₃ colloids according to equilibrium in 
Reaction (2), with the resulting aluminium yield decreasing as 
the NaOH concentration increases. No solid is formed at NaOH 
: Al(NO₃)₃·9H₂O molar ratios above 5.2 due to the absence of 
Al(OH)₃ during the hydrothermal conditions according to 
Reaction (2).

**Figure 3** Effect of the initial NaOH : Al(NO₃)₃·9H₂O molar ratio during 
hydrothermal synthesis (200°C, 20h) on the final γ-Al₂O₃ yield (wt. %).

As discussed before, the NaOH : Al(NO₃)₃·9H₂O molar ratio 
also determines the resulting morphology of the products, 
making it possible to selectively obtain nanorods under acidic 
hydrothermal conditions (pH ~3.5) and nanoplates under basic 
conditions (pH ~12.8). In the cases where high morphological 
purity is achieved, the alumina yield does not exceed 50 %. 
Higher alumina yields result in a mixture of nanorods and 
nanoplate morphologies. In order to increase the overall 
alumina yield and in an effort to reduce solvent waste and 
increase atom efficiency, the recyclability of the synthesis 
solution was investigated. 
For this, a boehmite synthesis with an initial NaOH 
concentration of 1M (pH 3.5) was carried out producing 
uniform nanorods with a final alumina yield of 43 %. After 
separation of the product, the synthesis medium was reused 
prior to addition of fresh precursors (Al(NO₃)₃·9H₂O and 
NaOH). Highly uniform boehmite nanorods were obtained, 
increasing the alumina yield to 90 % at least in four consecutive 
recycles. The morphology of the resulting γ-AlOOH and γ-
Al₂O₃ materials from the consecutive assay are shown in Figure 
4. The reusability of the reaction medium is applicable to all 
the hydrothermal syntheses with different initial NaOH 
concentration studied herein as illustrated by a similar example 
at an initial pH of 4.6 (3.9 M NaOH), where a mixture of 
nanorods and nanoplates are produced (Figure 4).

**Figure 4** Initial nanostructured γ-AlOOH hydrothermally synthesised (200°C, 20h) 
at a) pH 3.5 and b) 4.6 and morphology of γ-AlOOH synthesised by recycle 
procedure from initial pH c) 3.5 and d) 4.6. e) and f) show the morphology of 
resulting γ-Al₂O₃ samples after calcination of c) and d) respectively.

The X-ray diffraction patterns shown in Figure 5 confirm the 
synthesis of orthorhombic boehmite materials during the 
hydrothermal treatment with major diffraction peaks at 2θ 
values of 15, 28, 38, 48, 55 and 60° (JCPDS 21-1307). 
However, as the hydrothermal pH conditions increase, 
additional diffraction peaks appear at 2θ values of 23, 35, 43, 
52, 56 and 62°, which cannot be attributed to the boehmite 
crystal structure. These peaks are believed to be related to the 
presence of residual Na from the high concentration of NaOH 
used in these conditions. This is further evidenced by EDS 
chemical analysis of the boehmite materials in which the 
nanorods synthesised under acidic hydrothermal conditions 
show the presence of only Al and O elements indicative of pure 
γ-AlOOH, whereas basic synthetic conditions yielded γ-AlOOH 
containing Na. Especially significant is the diffraction peak at 
2θ value of 29° present in both, the boehmite and alumina 
nanoplates (Figure 5b and d). A peak at the same diffraction 
angle was previously observed for another metal oxide, PbO, 
with increasing peak intensity as the concentration of NaOH 
increased. Indeed, the presence of Na in the product material 
is even more evident after reusing of the solvent due to the 
accumulation of Na cations (and nitrates anions). However, it is 
important to highlight that this accumulation does not have an 
apparent effect on the morphology of the resulting material. 
Further re-usability cycles are however needed for a better
understanding of the potential effect of Na and nitrate concentration on the reaction steps described above.

![Figure 5](image)

Figure 5 Assigned X-ray diffraction pattern for γ-AlOOH a) nanorods and b) nanoplates synthesised under acidic and basic conditions respectively (200ºC, 20 hours) and γ-Al₂O₃ c) nanorods and d) nanoplates. (Acidic = pH 3.5, basic = pH 12.8)

The N₂ adsorption-desorption isotherms of boehmite and alumina nanorods synthesised under hydrothermal acidic conditions are shown in Figure 6. The isotherm shows the presence of some microporosity and mesoporosity. The corresponding pore size distribution shows a bimodal distribution with pores < 2 nm corresponding to the porosity within the 1D material as well as a broad peak (10 – 40 nm) corresponding to the voids between the 1D rods. The subsequent BET surface area for boehmite and alumina synthesised at pH 3.5, 4.6 and 12.8 is summarised in Figure 7. It is interesting to note the increase in BET surface area as a result of the transformation of boehmite into alumina by calcination, the effect of which is most prevalent for boehmite synthesised at pH 3.5. The relationship between an increased synthesis pH and the corresponding lower BET surface area has been previously reported in the literature.¹⁰

![Figure 6](image)

![Figure 7](image)

Figure 7 BET specific surface area for boehmite (white) and alumina (grey) hydrothermally synthesised at pH 3.5, 4.6 and 12.8 for 20 hours at 200°C.

The surface area of the boehmite and the corresponding alumina synthesised with a recycled synthesis medium decreases from 46 to 30 m²/g in the case of γ-AlOOH. The change in the physical properties are due to the alterations of the NaOH : Al(NO₃)₃·9H₂O molar ratio and pH during consecutive hydrothermal treatment. In any case, the remarkable enhancement of the aluminium yield and production as well as the avoidance of waste solvent production
set the foundations for further investigations to determine a feasible manufacturing route for continuous synthesis of high purity nanostructured $\gamma$-Al$_2$O$_3$.

Conclusions

The results presented herein and the understanding of the reaction steps during hydrothermal synthesis of nanostructured alumina establish that the resulting $\gamma$-Al$_2$O$_3$ morphology and yield is dependent not only upon the solution pH but also the NaOH : Al(NO$_3$)$_3$$\cdot$9H$_2$O molar ratio. Highly crystalline $\gamma$-Al$_2$O$_3$ nanorods with high morphological purity are synthesised by hydrothermal treatment at initial pH 3.5 and 1:1 reactant ratio for 20 hours at 200 °C. Conversely, $\gamma$-Al$_2$O$_3$ nanoplates with heterogeneous sizes are formed as a result of the same hydrothermal procedure with initial pH 5.9 and NaOH : Al molar ratio of 4.6. The synthetic procedure has been demonstrated to be viable for manufacturing scale up by recycling of the reaction solution, maximizing the use of precursors (yield) and productivity and reducing solvent waste.
