24 **Abstract**

25 Current techniques for diagnosing early loosening of a total hip replacement (THR) are
26 ineffective, especially for the acetabular component. Accordingly, new, accurate, and
27 quantifiable methods are required. The aim of this study was to investigate the viability of
28 vibrational analysis for accurately detecting acetabular component loosening.

29 A simplified acetabular model was constructed using a Sawbones® foam block. By placing a
30 thin silicone layer between the acetabular component and the Sawbones block, 2- and 4-mm soft
31 tissue membranes were simulated representing different loosening scenarios. A constant
32 amplitude sinusoidal excitation with a sweep range of 100–1500 Hz was used. Output vibration
33 from the model was measured using an accelerometer and an ultrasound probe. Loosening was
34 determined from output signal features such as the number and relative strength of observed
35 harmonic frequencies.

36 Both measurement methods were sufficient to measure the output vibration. Vibrational analysis
37 reliably detected loosening corresponding to both 2 and 4 mm tissue membranes at driving
38 frequencies between 100 and 1000 Hz ($p < 0.01$) using the accelerometer. In contrast, ultrasound
39 detected 2-mm loosening at a frequency range of 850–1050 Hz ($p < 0.01$) and 4-mm loosening at
40 500–950 Hz ($p < 0.01$).

47

48 **1. Introduction**

49 One million total hip replacement (THR) operations are conducted annually worldwide, and this
50 number is predicted to increase [1]. Within the first ten years of THR, around 10% of all
51 implants are expected to fail, with loosening being the most common reason [2]. The diagnostic
52 approaches to detect loosening are generally categorised into two groups: imaging and non-
53 imaging approaches [3].

54 Radiology is the most commonly used diagnostic method and consists of different sub-
55 techniques that can be used depending upon need. These techniques generally inspect the bone
56 and implant interfaces to identify osseointegration, failure, or fractures [4]. However, due to the
57 diffraction effects associated with x-ray scattering, it may be difficult to diagnose early loosening
58 using radiological imaging techniques, especially for the acetabular component [5, 6]. Even
59 though imaging has a sensitivity and specificity of up to 80% for loosening detection, revision
60 operations on a well-fixed implant may still occur [7].

61 Vibration analysis is a mechanical non-destructive technique that is widely used to inspect
62 composite materials and structural integrity, and it has been successfully expanded into the arena
63 of biomechanics [5]. This technique predominantly measures the response to low-frequency
64 excitation that is reflected from the targeted surface or structure [8]. In the early 1930s,
65 Lippmann [9] pioneered vibration analysis in medical research, utilising the stethoscope to
66 examine bone fractures and using his fingers to elicit the input vibration. As technology
67 developed, research groups had better tools at their disposal to investigate and develop a clinical
68 diagnostic instrument; this was realised in the works of Chung et al. [10] and Poss et al. [11],
69 who used vibration analysis to study the process of prosthetic fixation using bone cement. They
70 implied that by using vibration analysis and monitoring the resonance frequency shift
71 phenomena, it is possible to estimate implant fixation states. In this scenario, the implant
72 osseointegration process is reflected by a gradual increase in the frequency response. Further

73 studies also were conducted [12-19] to measure the dynamic properties of the implant in order to
74 identify different interference changes.

75 Rosenstein et al. [20] were one of the first groups to utilise vibration analysis both *in vivo* and *in*
76 *vitro* in a clinical study. They showed that a secure prosthesis would respond with a single
77 frequency vibration, whereas a loose prosthesis would vibrate at different frequencies appearing
78 as different peaks in the frequency spectrum; this vibration analysis concept is simplified for the
79 acetabular component, as presented in Figure 1.

80 Li et al. [21, 22] were the next to explore vibration analysis, showing that the early prosthetic
81 loosening diagnosis has a poor sensitivity (37.5%), but that it could reliably detect late loosening.
82 Georgiou and Cunningham [23] also compared vibration analysis with standard radiological
83 assessment and demonstrated that vibration analysis improved diagnostic precision by 20%;
84 moreover, they were able to detect 13% more cases than radiological diagnosis with 81%
85 sensitivity and 89% specificity. Other research groups have used vibration analysis for different
86 orthopaedic applications such as; the telemetry technique to assess THR femoral loosening [24-
87 26], trans-femoral osseointegration [27-29], intra-operative initial implant stability [6,30-33],
88 THR femoral stability utilising acoustic resonance responses [7, 34-41], and complete THR
89 component loosening (femoral and acetabular) [5].

90 Rowlands et al. [42] investigated replacement of the accelerometer sensor with an ultrasound
91 probe to overcome the effect of soft tissue damping. Their approach used excitation frequencies
92 < 1500 Hz on two different types of bone analogues, Sawbones® and Tufnol®. Initially, the
93 Sawbones femur was tested with both a fixed and loose hip prosthesis by using cement fixation.
94 The Tufnol femur was then tested for three interface conditions by using different diameter solid
95 bars of varied fits (fixed, sliding, and loose). Ultrasound distinguished between the secure and
96 loose states with a noticeably higher signal magnitude than the accelerometer.

97

98 The majority of previous studies on vibration analysis [20-24, 35-42] assessed loosening of the
99 femoral stem. Since a high rate of loosening in the acetabular component has been reported in
100 the clinically [43]; therefore, the aim of the present study was to compare ultrasound and
101 accelerometer methods and to examine the viability of the vibration analysis technique to
102 accurately detect acetabular component loosening.

103

104 **2. Materials and methods**

105 A simplified model was constructed to mimic different scenarios of acetabular cup loosening.
106 A secure component was represented by a tight press-fit of the acetabular cup in polyurethane
107 solid foam (Sawbones) blocks with a hemispherical cavity. By placing a thin layer of low
108 modulus silicone (EVO-STIK, Bostik Limited, England) between the acetabular component and
109 the Sawbones block, the loosening effects of 2 and 4 mm soft tissue interfaces were simulated.
110 To represent healthy bone density, blocks with a density of 0.48 g/cm³ (Sawbones Europe AB,
111 Malmö, Sweden) were used, with two acetabular cups having outside diameters of 54 and 52
112 mm, respectively (Trident® Hemispherical cup, Stryker Orthopaedics, Mahwah, New Jersey,
113 USA), as shown in Figure 2.

114

115 The secure Sawbones block cavity (diameter 53 mm) was machined using a computer
116 numerically controlled (CNC) milling machine. Subsequent cavities to simulate loosening were
117 created using acetabular reamers to give cup cavity diameters of 56 and 60 mm. This created a
118 gap between the cup shell and the block cavity surface, as shown in Figure 3. The secure
119 acetabular cup scenario (0-mm loosening) involved using the 54-mm acetabular cup press-fitted
120 in a 53-mm diameter Sawbones block cavity until it was immovable. The 2- and 4-mm loose cup
121 scenarios were produced using the 52-mm acetabular cup placed into Sawbones blocks with cup
122 cavity diameters of 56 and 60 mm, respectively, as shown in Figure 3. In both loosening
123 scenarios, a silicone layer between the acetabular cup and the Sawbones interface was used to
124 mimic the soft tissue interface in accordance with previous studies [21, 22]. Each scenario was

125 exposed to a vibration sweep range of 100–1500 Hz using a mini shaker (V201, LDS Ltd, UK).
126 The Sawbones block setup was lightly suspended to create a repeatable boundary condition,
127 (Figure 4a).

128

129 **2.1 Excitation Signal**

130 A function generator (TG230, Thurlby Thandar Ltd, UK) connected to a power amplifier
131 (PA25E, LDS Ltd, UK) was used for vibration excitation via a mini-shaker (V201, LDS Ltd,
132 UK). The excitation signal was a constant amplitude sinusoidal wave with a frequency sweep
133 range of between 100 and 1500 Hz, with incremental steps of 50-Hz. The shaker was positioned
134 in a similar location on the Sawbones block for all tests (Figure 4b).

135

136 **2.2 Measurement and analysis**

137 An ultrasound transducer (Mini Dopplex 500 4 MHz, Huntleigh Technology Plc, UK) and
138 accelerometer (Model 353B18; PCB Piezotronics Inc, US) were used to measure the output
139 vibration. Consistent with other orthopaedic vibration studies [5, 20-23], the accelerometer was
140 used as a reference measurement method. Ultrasound was chosen as an alternative measurement
141 method due to its capacity to overcome the attenuating effect of the soft tissues surrounding the
142 implant in the clinical environment [42].

143

144 The ultrasound and accelerometer data were recorded using a custom code in LabVIEW (Sound
145 and Vibration Measurement Suite version 11, National Instruments) via a USB data acquisition
146 system (USB-4431, National Instruments) using a personal computer (Core2Duo 3.16 GHz, CPU
147 4 GB RAM). The resulting natural frequency spectrum of both measurement methods was then
148 observed using a fast Fourier transform (FFT) to define the optimum frequency excitation range
149 using two simultaneous measurement methods; twelve measurements were obtained at 50-Hz
150 increments from each of the fixation scenarios (0-, 2-, and 4-mm loose) under the sinusoidal
151 frequency sweep. Insufficient sampling frequency may result in distortion from the original

152 continuous signal, which is known as the aliasing effect. Thus, a sampling frequency of 8 kHz
153 was used to overcome this effect. The accelerometer was coupled to the block surface using a
154 petro-wax, and ultrasound gel was used to couple the ultrasound probe. Each measurement was
155 taken from a specifically defined location on the Sawbone block for accuracy and repeatability
156 (Figure 4). Analysis was conducted in two stages as explained below: the spectrum analysis and
157 the harmonic ratio.

158

159 **2.2.1 Spectrum Analysis**

160 Real-time spectrum analyses tracked the frequency response and observed relationships between
161 the two loosening scenarios and the secure condition across the different driving frequencies. For
162 the secure implant, vibration analysis implies that the frequency response would be similar to the
163 excitation signal, whereas for the loose condition, the response would be distorted with multiple
164 apparent harmonics. This was accomplished using two frequency variables: the fundamental
165 frequency (F_o) and the first harmonic (F_1). The main response to the driving frequency is the
166 fundamental frequency, whereas the first harmonic is indicative of system nonlinearity.

167

168 **2.2.2 Harmonic Ratio**

169 In an attempt to define the optimum frequency excitation range for the loosening assessment, a
170 sweep analysis was conducted. The resulting frequencies were then analysed as the harmonic
171 ratio, defined as the relative magnitude of the first harmonic to the fundamental frequency
172 (Harmonic Ratio = First Harmonic [F_1] magnitude/Fundamental Frequency [F_o] magnitude).
173 This ratio can then be utilised to show how the different loosening conditions affect the relative
174 magnitude of the first harmonic across the different driving frequencies.

175

176 **2.3 Statistics**

177 Statistical analysis was performed using SPSS software (version 20.0; SPSS, Chicago, IL, USA).
178 A Shapiro-Wilk test revealed that the harmonic ratio data were not normally distributed; thus,

179 non-parametric analyses were performed. The conditions (0, 2, and 4 mm) were compared at
180 each frequency step using a Kruskal-Wallis test, and Mann-Whitney U-tests were used for post-
181 hoc analysis. Significance was defined as a p value of <0.05.

182

183 **3. Results**

184

185 **3.1 Spectrum analysis**

186 The initial variable in the FFT spectrum analysis was the fundamental frequency (F_o) magnitude
187 that changed in relation to the cup stability. The frequency magnitude was assessed based on the
188 root mean squared (RMS) value over the excitation period. Figure 5 shows the output
189 measurement response of three simulated loosening conditions at a driving frequency of 200 Hz
190 for both the ultrasound and accelerometer. It was noted that the secure condition had the highest
191 fundamental frequency magnitude, followed by the 2- and 4-mm loose conditions, respectively.
192 However, when examining the readings for both the ultrasound and accelerometer, the absolute
193 magnitude of the reduction in vibration magnitude with loosening is higher for the ultrasound
194 readings than for the accelerometer readings, as shown in Figure 5.

195

196 The next variable examined was the first harmonic (F_1), which behaves in a manner opposite to
197 the fundamental frequency (F_o). The magnitude of the first harmonic peak increased relative to
198 the degree of acetabular cup loosening. For example, in Figure 5, the first harmonic with 4-mm
199 loosening had a higher magnitude than for 2-mm loosening. When comparing the absolute
200 magnitude of the first harmonic using the two measurement methods, the ultrasound results were
201 able to discern more harmonics than the accelerometer results, enabling a clear distinction
202 between the loosening scenarios.

203

204 The above findings indicated that as the gap between the Sawbones block and cup increased
205 (representing increased loosening), the system became more non-linear, which was reflected in

206 the lower fundamental frequency and higher harmonic peak values. These harmonic readings
207 correlated with the finding of Rowlands et al. [42], who reported that the presence of harmonics
208 can be used as an indication of loosening, which could be detected using either the
209 accelerometer or ultrasound transducers , especially for frequencies < 500 Hz with stem
210 component .

211

212 **3.2 Harmonic ratio**

213 The harmonic ratio measurement for the three simulated conditions by using ultrasound and
214 accelerometer was illustrated alongside each other using the median \pm 95% confidence interval
215 for ease of comparison. The Mann-Whitney test was used to determine significance (defined as p
216 < 0.05), as shown in Figure 6.

217

218 **3.2.1 Accelerometer**

219 The harmonic ratios for the accelerometer are shown in Figure 6a. The ratios clearly showed a
220 pattern, according to which the secure cup had the lowest value, followed by 2-mm loosening,
221 and 4-mm loosening having the highest harmonic ratio in the frequency range up to 950 Hz. The
222 harmonic ratio for 2-mm loosening was significantly greater ($p < 0.01$) than that in the secure
223 condition in the driving frequency range 100–1050 Hz (Figure 6c). For 4-mm loosening, the
224 harmonic ratio was significantly greater ($p < 0.01$) than that in the secure condition in the
225 frequency range 100–1000 Hz (Figure 6e). When comparing the two loosening conditions, the 4-
226 mm loosening condition resulted in a significantly higher harmonic ratio ($p < 0.05$) in the
227 frequency ranges 150–250 Hz and 550–900 Hz.

228

229 **3.2.2 Ultrasound**

230 The harmonic ratio derived from ultrasound measurements had a higher magnitude than the
231 accelerometer readings, as shown in Figure 6 a-b. The ultrasound measurements were between
232 200 and 1500 Hz due to the ultrasound system's built-in filter that affected readings below 200

233 Hz. The same pattern was observed with the accelerometer, with the lowest harmonic ratio
234 observed in the secure condition and progressively increasing at 2- and 4-mm loosening,
235 respectively. The 2-mm loosening resulted in a significantly higher harmonic ratio ($p < 0.01$)
236 than that in the secure condition at driving frequencies between 850 and 1050 Hz (Figure 6d).
237 The harmonic ratio of the 4-mm loosening condition was significantly higher ($p < 0.01$) than that
238 in the secure condition between 500 and 950 Hz (Figure 6f). The harmonic ratio for 4-mm
239 loosening was significantly greater ($p < 0.05$) than that for 2-mm loosening between 500 and 700
240 Hz and between 800 and 850 Hz.

241

242 **4. Discussion**

243 Most THR stability assessment studies have focused on the femoral component [20-24, 35-42].
244 Vibration analysis studies on acetabular loosening are limited because the acetabulum has a
245 complex geometry compared to the femur and has a thicker overlaying soft tissue layer, which
246 acts as a signal buffer. Thus, the aim of this study was to explore the viability of vibration
247 analysis to accurately detect acetabular component loosening.

248

249 Vibration analysis implies that secure implants respond with a single frequency peak similar to
250 the excitation signal, whereas loose implants vibrate at different frequencies, which appear as
251 multiple harmonics peaks in the frequency spectrum. The resulting frequencies were initially
252 observed using FFT analysis, then analysed as the harmonic ratio, which was subsequently used
253 as a novel method to track frequency responses and observe relationships between the loosening
254 scenarios and the secure condition across frequencies of 100–1500 Hz. Using this approach, the
255 three simulated conditions were distinguishable at an excitation frequency range of 200–950 Hz,
256 using both ultrasound and the accelerometer.

257

258 Most orthopaedic vibration studies have used FFT spectrum analysis to assess implant loosening
259 [20-23, 42]. However, most examined the stem component and reported that implant instability

260 can be identified through harmonics in the frequency spectrum (Figure 1). Moreover, they
261 highlighted that the lower frequency range (≤ 1000 Hz) had the most potential for stability
262 assessment [20, 23]. Rieger et al. [5] assessed a complete THR (femoral and acetabular implants
263 in a Sawbones femur and hemi-pelvis) and detected acetabular cup loosening at frequencies of
264 450 and 600 Hz. At these frequencies, a noticeable resonance shift was observed when the
265 loosening condition was compared with the secure condition using an accelerometer and laser
266 vibrometer. Using an FFT analysis, the present study revealed the same overall conclusions. The
267 difference between the three simulated conditions was observed using two frequency variables:
268 the fundamental frequency (F_0) and the first harmonic (F_1). The fundamental frequency was
269 primarily in response to the driving frequency, and the first harmonic indicated the level of
270 instability. The three simulated conditions examined with FFT analysis at a driving frequency of
271 200 Hz demonstrated that, as loosening increases, the system becomes increasingly non-linear,
272 which is reflected at the lower fundamental frequency and higher harmonic peak magnitude
273 (Figure 5).

274

275 Another novel contribution of this study is the use of the harmonic ratio to quantify the FFT
276 spectrum analysis frequency response across the 100–1500 Hz range. This ratio represents the
277 relative magnitude of the first harmonic to the fundamental frequency. When analysing the
278 harmonic ratio for the accelerometer and ultrasound measurements at frequencies < 950 Hz, a clear
279 pattern was observed. The secure cup had the lowest ratios and, as the loosening progressed, this
280 ratio increased. At excitation frequencies of 100–1050 Hz, the accelerometer detected loosening
281 corresponding to 2 mm between the cup shell and the Sawbones surface, while 4 mm loosening
282 was detected at excitation frequencies of 100–1000 Hz. In agreement with the study of Rowlands
283 et al. [42] which examined stem loosening, as opposed to acetabular loosening in the current study,
284 the ultrasound measurements were clearly higher than accelerometer readings throughout the
285 frequency range. However, because of the increased variability of ultrasound measurements
286 compared to measurements with the accelerometer, a significant difference between the secure and

287 loose conditions was only established at the high frequency range. Loosening of 2 mm was
288 detected at driving frequencies of 850–1050 Hz, while 4-mm loosening was detected at 500–950
289 Hz. Therefore the harmonic ratio was clearly able to discern between the simulated conditions
290 using both measurement methods.

291

292 The use of single density Sawbones block to mimic different loosening conditions was an
293 attempt to simplify acetabular cup instability, which could be considered as a limitation.

294 Additionally, the exaction method was positioned closer to the acetabular component than would
295 be possible in a clinical setting. Moreover, the loosening conditions had only press-fit acetabular
296 cups with hard shell components. Future experiments will try to overcome these limitations by
297 moving towards a more clinically realistic setup. Initially, this will involve using a Sawbones
298 hemi-pelvis with an implanted THR cup, followed by a combined pelvis and femur containing a
299 complete THR [5]. On successful completion of these experiments a further aim would be to
300 carry out a pilot clinical study.

301

302 **5. Conclusion**

303 This work has demonstrated that vibration analysis can be used to detect acetabular cup
304 component loosening in a simplified *in vitro* model using either the accelerometer or ultrasound
305 to measure output vibration. The harmonic ratio is a novel and useful parameter for comparing
306 output signals to easily discern between secure and loose cups. Further experiments will be
307 required to overcome current study limitations and achieve a more realistic setup for loosening
308 scenarios.

436 **Figure captions**

437 Figure 1: Vibration analysis concept showing the difference between the secure and loose
438 acetabular cup prostheses.

439 Figure 2: The Sawbones block showing the excitation and measurement methods.

440 Figure 3: The three simulated testing conditions of 0, 2, and 4 mm of loosening.

441 Figure 4: The experimental setup showing the Sawbones block, excitation, and measurement
442 methods.

443 Figure 5: FFT spectrum analysis at 200 Hz showing the difference between the secure prosthesis,
444 2 mm loose condition, and 4 mm loose condition for the ultrasound and accelerometer readings.

445 Figure 6: The harmonic ratio of the different loosening conditions using an accelerometer and an
446 ultrasound probe as the measurement methods. *Graphs a, c, and e* used an accelerometer for the
447 loosening conditions of (0 mm, 2 mm, and 4 mm), (0 mm and 2 mm), and (0 mm and 4 mm),
448 respectively. *Graphs b, d, and f* used an ultrasound for the loosening conditions of (0 mm, 2 mm
449 and 4 mm), (0 mm and 2 mm), and (0 mm and 4 mm), respectively. *Mann-Whitney test $p <$
450 0.05.
