Abstract

In this paper we tackle the problem of capturing the dense, detailed 3D geometry of generic, complex non-rigid meshes using a single RGB-only commodity video camera and a direct approach. While robust and even real-time solutions exist to this problem if the observed scene is static, for non-rigid dense shape capture current systems are typically restricted to the use of complex multi-camera rigs, take advantage of the additional depth channel available in RGB-D cameras, or deal with specific shapes such as faces or planar surfaces. In contrast, our method makes use of a single RGB video as input; it can capture the deformations of generic shapes; and the depth estimation is dense, per-pixel and direct. We first compute a dense 3D template of the shape of the object, using a short rigid sequence, and subsequently perform online reconstruction of the non-rigid mesh as it evolves over time. Our energy optimization approach minimizes a robust photometric cost that simultaneously estimates the temporal correspondences and 3D deformations with respect to the template mesh. In our experimental evaluation we show a range of qualitative results on novel datasets; we compare against an existing method that requires multi-frame optical flow; and perform a quantitative evaluation against other template-based approaches on a ground truth dataset.

1. Introduction

The recent emergence of low cost depth sensors, has brought easy and fast acquisition of 3D geometry closer to reality. Systems such as KinectFusion [20] allow users to scan the detailed 3D shape of rigid scenes. The use of RGB-D sensors has also been extended to markerless capture of non-rigid shapes [14, 15] even in real time [18, 37]. At the same time, many multi-camera techniques for marker-less high-end dynamic 3D shape acquisition have been developed over the last decade [8, 33].

In contrast, the acquisition of dense 3D models of generic deformable meshes from a monocular RGB-only video stream is significantly harder. The ability to acquire time-varying dense shapes from monocular RGB video would open the door to easy, lightweight non-rigid capture and, perhaps more importantly, from existing video footage or web-based video libraries such as YouTube.
While spectacular progress has been made in monocular dense 3D reconstruction of static scenes from video [19, 28, 13, 31], direct 3D capture of dense non-rigid shapes from a single video stream lies significantly behind.

Three main successful directions dominate the literature for monocular 3D reconstruction of deformable surfaces. Model-based methods [3] use blend-shape models learned from 3D training data in an off-line training step. Non-rigid structure from motion (NRSfM) approaches offer a model-free formulation for generic shapes but require long term correspondences across a video sequence [4, 7, 10, 22, 23, 32] and are typically batch methods that process the entire sequence at once. Finally, shape-from-template approaches [2, 21, 24, 26] offer an attractive sequential frame-to-frame solution but they require a known 3D reference template of the surface and point correspondences between each new frame and the template as input. In addition they have mostly been demonstrated only on simple planar meshes of objects such as paper and cloth.

Two common limitations remain with most NRSfM and shape-from-template formulations: (i) they are typically feature-based which leads to sparse reconstructions or failure with low-textured surfaces and (ii) estimation of 2D correspondences and 3D shape inference are decoupled and not solved simultaneously in a direct approach. So far the problem of jointly estimating dense point correspondences and non-rigid 3D geometry from monocular video has received very little attention. Garg et al. demonstrated a dense per-pixel NRSfM approach but it required dense 2D correspondences to be pre-computed using a multi-frame optical flow method. Pixel-based approaches to template-based reconstruction have been proposed by Malti et al. [16] and Suwajanakorn et al. [30] but they were only demonstrated on planar surfaces (cloth or paper) [16] or worked exclusively for faces [30].

In this paper we adopt a template-based direct approach to deformable shape reconstruction from monocular sequences. Our contribution is an end-to-end system that builds a dense template from an initial rigid subsequence and subsequently estimates the deformations of the mesh with respect to the 3D template by minimizing a robust photometric cost. Unlike previous template-based direct methods [16, 30] we demonstrate our approach on a variety of generic complex non-planar meshes. While our algorithm is not real-time, it is sequential and relatively fast, typically requiring 3 seconds per frame on a standard desktop machine to optimize a mesh with approximately 25,000 vertices. Ours is the only template-based approach that satisfies all the properties listed in Table 1.

2. Related Work

Very few methods attempt dense and direct reconstruction of non-rigid shapes from monocular sequences. There are three areas of research that have inspired and influenced our work: non-rigid structure from motion, shape-from-template and RGB-D based non-rigid capture. We now describe the most related approaches from each of these fields.

The most related NRSfM method to ours is the dense monocular non-rigid reconstruction algorithm by Garg et al. [10]. Although their algorithm reconstructs dense per-pixel models, noticeably, it is a batch process that requires multi-frame optic flow over the entire sequence as an input. No attempt was made to solve the dense correspondence and reconstruction problems simultaneously. As such, if the

flow generation fails, a good reconstruction is not possible.

Our method also shares strong similarities with work in the area of shape from template [2, 24, 21, 26]. Many approaches have been proposed mostly taking advantage of the constraints imposed by isometric or conformal deformations [2, 17, 25]. While most template approaches are feature-based and only reconstruct based on a small number of points, Malti et al. [16] departs by proposing a direct pixel-based variational framework that exploits visibility constraints. However, their method was only demonstrated on flat isometric surfaces. The recent work of Suwajanakorn et al. [30] reconstructs RGB-only videos of faces of celebrities. Similarly to our method, they formulate template-based non-rigid reconstruction as a frame-to-frame energy minimization that optimizes a direct photometric cost. However, their method is limited to reconstructing human faces as their template reconstruction approach is specifically tailored to them. Also related is the monocular face capture system of Garrido et al. [11]. While their work also minimizes a photometric cost and the deformations with respect to a template model, theirs is a sophisticated blend-shape model specifically built to capture the deformations of human faces.

Our work has been largely inspired by recent advances in non-rigid tracking using depth cameras [18, 37]. Zollhofer et al.’s [37] is the most related approach since their setup is directly comparable to ours — a multi-scale template is built first from a rigid sub-sequence, followed by dense non-rigid monocular tracking. However, while their method uses both the depth and the RGB channels, ours only uses RGB images as input and can be seen as its RGB-only equivalent.

Table 1 summarizes our main contributions and the differences with respect to the four most closely related approaches. In summary, ours is the only RGB-only, template-based, monocular, dense and direct approach to non-rigid reconstruction that is sequential and suitable for generic shapes and closed meshes.

3. Problem Formulation

We consider a perspective RGB camera with known internal calibration observing a non-rigid mesh deforming over time. The goal of our algorithm is to estimate, at each time-step \( t \), the current 3D coordinates of the \( N \) vertices of the dense non-rigid mesh \( S_t = [s_1, \ldots, s_i, \ldots] \), \( i = 1..N \), as well as the overall rigid rotation and translation \((R, t)\) that align the deformed shape and a reference 3D template.

The only inputs to our algorithm are the current RGB image \( I(x, y) \) observed at time \( t \) and a template shape \( \tilde{S} = [\tilde{s}_1, \ldots] \), \( i = 1..N \), which is acquired automatically in a preliminary template acquisition step using the multi-view stereo dense volumetric approach of [5]. Typically the user acquires a short rigid sequence to capture the 3D coordinates of the template mesh which is then subsampled to create a multi-resolution hierarchy of coarse-to-fine templates. The template acquisition step is described in detail in section 4. The template is converted to a quadrilateral mesh, consisting of \( N \) vertices and \( M \) edges.

Once the template has been acquired, our system turns to perform frame-to-frame non-rigid alignment of the 3D shape given only the current frame as input. Although optimization is initialized using the shape from the previous frame \( S_{t-1} \), once the template has been generated, the optimization objective does not depend on any other frames. As such, unlike most approaches to non-rigid structure from motion [7, 10, 22, 32], it scales to the streaming of long sequences, with the complexity of optimization guaranteed to
Figure 4: Template acquisition step. **Left:** A volumetric representation is generated from stereo depth maps taken over a rigid subsequence. This is then transformed into a colored mesh. **Right:** The three scales of the template used to robustly estimate deformations.

grow linearly to the number of frames.

4. **Step 1: Template Shape Acquisition**

The first stage in our process is to obtain a rigid template mesh of the shape. We denote the whole shape as a $3 \times N$ matrix $\tilde{S}$, and $\tilde{s}_i$ as the $i^{th}$ vertex on the mesh. We require a set of $M$ images (we used $M \sim 30$) of the shape under a rigid transformation. These are obtained by subsampling a set of frames from a short video where either the object is static and the camera moves or the camera is static and the object is moved under a rigid transformation. Figure 4 provides an example of the output of this process.

The process of the template acquisition is an application of existing multi-view stereo (MVS) techniques; consequently we provide only an overview of the process with appropriate references to the methods used. A more detailed description of the process may be found in the supplementary material.

**Extrinsic Calibration** The collection of frames from the video were calibrated automatically using an implementation (VisualSFM [36]) of standard rigid structure-from-motion (SfM). This was observed to be robust to any incompatible motion in the background. If there is too much background clutter in the image then an automatic segmentation of the foreground can be attempted using a fixation condition (that the center of the image fixates on the object of interest) [6].

**Depth-Map Extraction** Once we have a calibrated set of frames, we extract a depth-map using the stereo method of [5]. For each (reference) image, we take the two closest viewpoints as neighboring images and extract the best $K = 9$ normalized cross-correlation (NCC) scores matching with $13 \times 13$ pixel windows. These are then filtered to provide a single depth estimate (or unknown label) using the default filtering parameters as specified in [5].

Figure 5: An example of our multi-scale template meshes generated by iterative mesh down-sampling and refinement. **Top:** From left to right the meshes contain approximately 5, 10, and 25 thousand vertices respectively. **Bottom:** The highest levels of the templates for the bobby and hand sequences.

**Mesh Estimation** The last stage is to extract the template mesh by combining all the individual depth-maps in a single global optimization. As suggested in [5], we combine the depth-maps to recover a single watertight mesh $\tilde{S}$ using the volumetric fusion technique of [35] combined with the probabilistic visibility approach of [12].

**Template Hierarchy** The output of the fusion stage is a watertight mesh $\tilde{S}$. From this we build a multi-scale representation of the mesh as shown in Figure 4 (right). This is achieved by iteratively down-sampling and refining the template mesh using the isotropic surface remeshing method.
(and implementation) of Fuhrmann et al. [9]. Finally, a color \( \hat{I}_i \) is associated to each vertex \( i \); this is the median color over all the frames in the rigid subsequence in which the projected vertex is visible.

To avoid aliasing when coloring the low resolution meshes, we blur each of the input images with a length-scale given by the median mesh edge length projected into the corresponding camera view. Figure 5 shows a triangulated example of the multi-scale colored mesh representation.

5. Step 2: Non-Rigid Model Tracking

5.1. Our Energy

Our objective is made of a balanced combination of four terms: (i) a photometric error which captures the expected color of each visible vertex in the template; (ii) a total variation term on the gradient of the 3D displacements with respect to the template (iii) as rigid as possible local regularization – this term allows the mesh to rotate locally without imposing a penalty and (iv) a temporal smoothness term that penalizes strong frame-to-frame deformations.

The per-frame objective takes the form:

\[
E(S, R, t) = E_{\text{data}}(S, R, t) + \lambda_r E_{\text{reg}}(S) + \lambda_s E_{\text{arap}}(S) + \lambda_t E_{\text{temp}}(S).
\]

where \( \lambda_r, \lambda_s, \) and \( \lambda_t \) denote the relative weights between the terms. These terms are all required. The first term guarantees that the deformations of the template follow the image; the second term encourages locally smooth deformations while allowing sharp discontinuities which are needed to transition from parts of the object that deform strongly to those that do not; while the third term encourages stronger changes in template depth. Finally, temporal smoothness is needed to avoid flickering.

\[
E_{\text{data}}(S, R, t) = \sum_{i \in V} \hat{I}_i - I(\pi(R(s_i) + t))_e,
\]

where \( \hat{I}_i \) is the color of vertex \( \hat{s}_i \) on the template mesh, \( I \) is the current image frame, \( V \) is the set of estimated visible vertices in the frame\(^1\), \( \{\hat{s}_i\}_{i=1}^N \) are the 3D vertices of the template, \( \{s_i\}_{i=1}^N \) are the 3D vertices of the shape in the current frame, \( \pi(\cdot) \) is again the projection from 3D points to image coordinates, known from camera calibration, and \( | \cdot |_e \) denotes the Huber loss, which takes the form

\[
|x|_e = \begin{cases} 
\frac{x^2}{2\epsilon} & \text{if } x^2 \leq \epsilon \\
|x| - \epsilon/2 & \text{otherwise.}
\end{cases}
\]

5.1.2 Spatial Regularization Term \( E_{\text{reg}} \)

The regularization term \( E_{\text{reg}} \) is a pairwise term that encourages spatially smooth deformations of the shape \( S \) with respect to the template \( \hat{S} \).

\[
E_{\text{reg}}(S) = \sum_{i=1}^{N} \sum_{j \in N_i} ||(s_i - s_j) - (\hat{s}_i - \hat{s}_j)||_e
\]

where \( N_i \) is the neighborhood of \( i \), and \( \| \cdot \|_e \) is the vector analog of the Huber loss formed by summing the standard Huber loss over all dimensions.

\(^1\)This is generated by realigning the deformed mesh of the previous frame to minimize photometric error (see section 5.2.1), and z-buffering.

</tbody>
</table>

For simplicity’s sake, we drop temporal super-scripts where appropriate as much of the formulation does not depend on any other frames. We now define each of the terms of the energy in detail.
5.1.3 As Rigid as Possible Deformation Term $E_{\text{arap}}$

This cost was first proposed in [27] to allow deformable tracking of an initial mesh against a depth map. It takes the form

$$E_{\text{arap}}(S, \{A_i\}) = \sum_{i=1}^{N} \sum_{j \in N_i} \| (s_i - s_j) - A_i (\hat{s}_i - \hat{s}_j) \|_2^2$$  (5)

where the variables $A_i$ are per-point local rotations. Essentially this cost allows for local rotations to take place in the mesh without penalty so long as the relative locations between points in the neighborhood of $i$ remain constant. It can be interpreted as a prior that allows for elastic style deformations of meshes.

5.1.4 Temporal Smoothness $E_{\text{temp}}$

The temporal regularization encourages smooth deformations from frame to frame and can be formulated as

$$E_{\text{temp}}(S, t) = \| S - S'^{-1} \|_F^2 + \| t - t'^{-1} \|_2^2$$  (6)

where $S'^{-1}$ and $t'^{-1}$ are the shape and the translation in the previous frame and $\| \cdot \|_F$ denotes the Frobenius norm of a matrix. The need for this term is most apparent when viewing a video of the reconstruction. Although a small amount of temporal regularization only alters the shape a little, it substantially reduces frame-to-frame flickering, while the temporal smoothness in the translation prevents explaining deformations as perspective effects.

5.2. Energy Optimization

For reasons of robustness and efficiency, optimization is performed in a two step form over rotations and translations, and shape separately, and using a 3-layer spatial pyramid.

5.2.1 Initialization

We optimize this objective in a two step form: first the rotations and translation are estimated using the shape from the previous frame.

$$E(R, t) = \sum_{i=1}^{N} \| \hat{I}_i - I(R(s_i'^{-1}) + t) \|_\epsilon$$  (7)

Then, holding the global rotations and translations constant, $s'$ is estimated. $R$, $t$, and at the coarsest level of the pyramid, $S'$ are initialized using their solution taken from the previous frame, and we perform optimization using a conjugate gradient based solver taken from Ceres [1].

5.2.2 Coarse-to-fine optimization

Both the rotation and translation cost (7), and the shape cost (1) are optimized over a set of 3-level coarse-to-fine images and shape templates, with each layer of the pyramid being a factor of two larger than the coarser layer directly above it. As we move down the pyramid from coarse to fine, the 3D vertices are propagated to the next level of the hierarchy using a prolongation step as described in Sumner et al. [29]. The weights are precomputed when the template mesh is created. Prolongation was also applied to the ARAP rotations $\{A_i\}$ using the method described in Zollhofer et al. [37].

6. Experimental Results

In this section we show qualitative results of our method on a variety of non-planar 3D meshes; a qualitative comparison with the dense NRSFM method of Garg et al. [10]; and
we provide a quantitative evaluation on the \textit{t-shirt} ground truth dataset from CVLab [34]. Our results can be best viewed in the accompanying video.\footnote{Please see \url{http://visual.cs.ucl.ac.uk/pubs/ddd/} for supplementary material and video.}

\textbf{Qualitative results on generic non-planar meshes} We show results on some new sequences acquired with a hand-held camera. We show sequences of a \textit{face} (Figure 1) and two soft toys – a \textit{bobby} (Figure 2) and a \textit{pig} (Figure 3). These sequences show a wide range of deformations of a varying set of shapes, with different degrees of elasticity. The reconstructions and deformations generated are convincing. To demonstrate our robustness to occlusions we manually augmented a sequence showing the tracking of a human hand with an artificial occluder (see Figure 10).

\textbf{Qualitative comparison with Garg et al. [10]} We show a direct qualitative comparison of the 3D deformable tracking (i.e. excluding the template generation) obtained using our approach with the reconstruction obtained with the dense NRSfM method of Garg et al. [10]. Our method, as presented, requires both known internal camera parameters and a static subsequence in which to generate the rigid template. Unfortunately neither of these are available for this face sequence. For this one sequence only, we follow [10] in assuming the camera is approximately orthographic, and generate a template by performing rigid SfM with bundle adjustment over the multi-frame optic flow used as input and made publicly available by Garg et al. [10].

The results can be seen in Figure 8. The advantage in not requiring optic flow as an input can be seen in the improved sharpness of the ear on the left and the smoother skin texture of our results. While the flow parameters must be chosen as a compromise between capturing the sharp movement of the ear, and dampening the flow fluctuations that appear in the face, our model based tracking has no such problems.\footnote{We speculate that owing to the implicit averaging in taking many frames to generate the rigid template, the template itself shows no such issues.} The other notable difference between our approach and theirs is that our computation is frame to frame instead of batch. Therefore, we naturally handle much longer sequences of thousands of frames while [10] does not scale well above 100 frames, with the dense optic flow method needed as in-
put as the main bottleneck. Despite being a direct approach, the quality of the reconstructions provided by our method is comparable to Garg et al., and in some situations arguably better (see Figure 8).

**Quantitative evaluation on the t-shirt dataset [34]** As a final experiment, we conduct a quantitative comparison against the template-based method of [34], obtaining less than half the numeric error of their approach (see Table 2, and Figure 6). The evaluation is carried out on a sequence of a t-shirt for which ground truth data was collected using a Microsoft Kinect RGB-D camera and made publicly available by [34].

7. Conclusion

We have presented a novel approach to template driven capture of dense detailed non-rigid deformations from video sequences. Our method solves simultaneously the 2D dense registration problem and the 3D shape inference using RGB-video and a pre-acquired template as only input. An additional advantage is that our approach is sequential in nature and can therefore be applied to arbitrarily long sequences. Unlike many other template based methods, our approach can deform complex generic meshes and is not restricted to planar surfaces. We have shown results on real world novel video sequences captured with a hand-held camera which demonstrate the validity of our approach; we compare against an existing method that requires multi-frame optical flow with comparable results; and perform a quantitative evaluation against other template-based approaches on a ground truth dataset where our approach halves the 3D error of competing approaches.
