A new algorithm for build time estimation for fused filament fabrication technologies

Zicheng Zhu, Vimal Dhokia* and Stephen T Newman
Department of Mechanical Engineering, University of Bath, Bath, United Kingdom, BA2 7AY

Abstract

The manufacture of highly complex and accurate part geometries with reduced costs has led to the emergence of hybrid manufacturing technologies where varied manufacturing operations are carried out in either parallel or serial manner. One such hybrid process being currently developed is the iAtractive process, which combines additive (i.e. fused filament fabrication, known as FFF†) and subtractive (i.e. CNC machining) processes. In the iAtractive process production, operation sequencing of additive and subtractive operations is essential. This requires accurate estimation of production time, in which the FFF build time is the determining factor. There have been some estimators developed for fused deposition modelling (FDM). However, these estimators are not applicable to hybrid manufacturing, particularly in process planning, which is a vital stage. This paper addresses the characteristics of FFF technologies, and develops a novel and rigorous method for predicting build times. An analytical model was first created to theoretically analyse the factors that affects the part build time, and was subsequently used to facilitate the design of test parts and experiments. The experimental results indicate that part volume, interaction of volume and porosity, and interaction of height and intermittent factor have significant effects on build times. Finally, the estimation algorithm has been developed, which was subsequently evaluated and validated by applying a wide range of the identified influential factors. The major advantage of the new proposed algorithm is its ability to estimate the build time based on simple geometrical parameters of a

† Fused Filament Fabrication (FFF) is sometimes called Fused Deposition Modelling (FDM). However, the latter term is trademarked by Stratasys Inc., and cannot be used publicly without authorisation from Stratasys.
given part. The key factors that drive the algorithm can be directly obtained from part dimensions/drawings, providing an efficient and accurate way for FFF time estimation. Test part evaluations and analysis has clearly demonstrated that estimation errors range from 0.1% to 13.5%, showing the validity, capability and significance of the developed algorithm and its applications to hybrid manufacture.

1 Introduction

Manufacturing technology has enjoyed rapid development with a number of evolutionary improvements over the past 60 years\(^1\). The ever-increasing demand for high quality products with low costs has led to the emergence of hybrid manufacturing technologies\(^2\)\(^-\)\(^3\). This new generation of manufacturing technologies integrate various different individual manufacturing processes on a single platform, exploiting their unique independent advantages whilst minimising the drawbacks\(^4\). A typical configuration of the hybrid processes is the combination of additive and subtractive processes\(^5\)\(^-\)\(^6\). Simhambhatla and Karunakaran\(^7\)\(^,\)\(^8\) used metal inert gas and active gas welding to build parts layer-by-layer. Once a layer was created, the surface was face milled in order to maintain a flat surface for the next welding operation. This process continued until the final shape of the part was generated. Nagel and Liou\(^9\), and Ren *et al.*\(^10\) incorporated a laser melting unit with a five-axis milling machine, where any deposition feature can be built in the horizontal direction by rotating the workstation. The milling process was used to significantly improve the surface quality and dimensional accuracy of the laser melted part. Lee *et al.*\(^11\) also integrated an additive unit (i.e. FDM) onto a desktop five-axis milling machine. The FDM extrusion
unit was placed on one end of the rotary axis and the cutter spindle was installed on the other end. Thus, the rapid switch between machining and FDM was realised by rotating the axis 180°C. Xiong et al. investigated the capability of a hybrid plasma deposition and milling (HPDM) process for the manufacture of complex free-from surfaces. The machine was equipped with a plasma torch and a milling head. After each layer was built by plasma deposition, it was subsequently machined to achieve high dimensional accuracy and surface quality.

Despite the capability of individual processes continuously improving, machining of highly accurate and complex structures without assembly is still considered to be extremely difficult due to limited cutting tool accessibility. A new concept currently being pioneered is the hybrid process, entitled iAtractive, for precision manufacture of complex part geometries. The iAtractive process consists of synergistically combining additive and subtractive (i.e. CNC machining) processes. Integrating the additive manufacturing (AM) technique provides the capability to manufacture complex part structures, such as internal cavities, which are virtually impossible to produce by CNC machining. Additionally, using CNC machining capabilities the final part can be produced by the iAtractive process with a high degree of accuracy comparable to that of an entirely CNC machined part. This paper is related to the build time estimation algorithm which is an integral part of the iAtractive process which itself is detailed in papers. The additive process integrated in the iAtractive process is termed fused filament fabrication (FFF), whereby material in filament form is fed into a liquefier chamber where it is heated to a semi-liquid state and deposited through a nozzle onto a build platform where it quickly solidifies. In a continuous process, the newly deposited material fuses with adjacent material that has already been deposited. Once a layer of the cross-section of the part has been completely deposited, the nozzle moves in positive Z a specified distance, which is the precise defined part layer thickness. The nozzle then starts depositing material to form the next layer. This process continues until a physical representation of the computer aided design (CAD) model is fully produced.
For manufacturing a part using both FFF and CNC machining, identifying an appropriate operation sequence is necessary. A feasible operation sequence could be as follows:

1. A part has three features, namely, Features A, B and C. Feature A is first built by FFF.
2. Subsequently, a machining operation is conducted to improve the dimensional accuracy and surface finish of Feature A.
3. This is followed by building Feature B onto the machined Feature A.
4. Feature C is built onto Feature B.
5. Finally, Features B and C are finished machined.

In fact, there are a number of feasible operation sequences that can be used to manufacture the above part. For example, in step 4, Feature B can be finish machined followed by building Feature C. Each operation sequence contains a number of FFF and machining operations, which will be carried out in a serial manner. In order to identify the most appropriate operation sequence in terms of production time, a time estimator is required. For the iAtractive process, the total production time is defined as the sum of the time used in FFF and the required machining operations. Machining time estimation has been extensively researched and some estimation models can be directly adopted. Readers are referred to the methods proposed by Wang et al., Heo et al. and So et al. In contrast, the FFF build time contributes to the majority of the total production time and FFF requires considerably more time than CNC machining. Therefore, reliable and accurate build time estimation becomes crucial for identifying suitable operation sequences for the iAtractive process.

This paper proposes and develops a new build time estimation algorithm for FFF. The two major requirements are estimation accuracy and efficiency, i.e. being able to accurately predict build times from a CAD model or 2D drawings which is the most accessible geometrical information for the iAtractive process. The state-of-the-art research on build time estimation is reviewed in section 2, which identifies
the existing estimation approaches. Section 3 proposes a method for developing the novel estimation algorithm for FFF technologies. An analytical model is developed in section 4, identifying the influential factors to build time. This model is used to accurately calculate the actual build times in the experiments documented in sections 5–7. A series of test parts with various combinations of features are then designed for developing and validating the estimation algorithm (sections 5–7). Rigorous statistical and algebraic analysis is carried out to identify the influential factors related to part geometries and material deposition tool paths.

2 Review of build time estimation research

This review provides state-of-the-art information pertaining to estimating build times for certain additive manufacturing processes.

Jin et al.\textsuperscript{20} developed a process planning approach for FDM and selective laser sintering (SLS) of components used in biomedical applications. This approach contained a time calculation model to estimate build times when using contour curve and zigzag tool path patterns to fabricate components. Han et al.\textsuperscript{21} theoretically analysed the deposition parameters and identified that layer thickness, deposition speed and deposition road width are the major parameters that determine the build time for FDM. Turner and Gold\textsuperscript{22} and Jin et al.\textsuperscript{23} further documented that shortening tool paths by optimising tool path patterns could minimise time. Pham and Wang\textsuperscript{24} discussed the interrelation between build time, roller travel speed, build height, laser scan speed, scan area and part volume in SLS. Subsequently an approximate build time estimation method was introduced, incorporating those key factors. Teitelbaum et al.\textsuperscript{25} proposed some design guidelines for FDM, which aimed to reduce cost and build time. These guidelines include minimising height and the number of overhangs and holes, maximising layer thickness, and building the object with the largest surface on the bottom. Yim and Rosen\textsuperscript{26} introduce approximate models for
estimating the cost and build time based on the geometric information of the given part design, particularly the part volume and the bounding box. These models can be applied to a number of processes including Stereolithography (SLA), SLS, FDM and ink-jet printing. One of the models were used to predict FDM build times for three test parts and the percentage errors were 9%, 12.5% and 11.8%, respectively. However, the estimation requires complicated calculations of deposition/scan length for each layer. Huang and Singamneni\textsuperscript{27}, and Nezhad \textit{et al.}\textsuperscript{28} pointed out that these models were usually time-consuming and not suitable for AM process optimisation where the adaptive slicing method is employed to reduce build time. Ghorpade \textit{et al.}\textsuperscript{29} developed a swarm intelligence approach to determining the optimal orientation of a part fabricated by FDM. The part orientation enables an appropriate surface finish to be achieved whilst reducing build time. In a paper by Kechagias \textit{et al.}\textsuperscript{30}, an algorithm for predicting build times for laminated object manufacturing (LOM) was presented, in which the part volume and surface area and the flat area were taken into account. The prediction errors were within 13.3\% of the actual build times. Instead of using an STL file to represent the part design, Campbell \textit{et al.}\textsuperscript{31} proposed a build time estimator, which is able to predict build times for the SLA process based on a 2D sketch with the average percentage error of 7.7\%. The build time of a part is calculated by using basic volumetric shapes in the sketch. Ruffo \textit{et al.}\textsuperscript{32, 33} proposed a build time estimator, which was integrated in a cost estimation model for SLS. This model consists of a series of empirical equations, calculating recoating, laser scanning, pre- and post-processing time. The maximum and average errors were found to be 13\% and 10.5\%, respectively, for the total build times. However, the maximum error reached 27\% when predicting the recoating time. Kumar and Regalla\textsuperscript{34} investigated the influence of the parameters (i.e. layer thickness, raster angle, orientation, contour width and raster width) on the build time and support material volume for an FDM process. The experimental results show that the increase of layer thickness and raster width tends to reduce the build time. Baumers \textit{et al.}\textsuperscript{35, 36} considered the time consumption of direct metal laser sintering (DMLS) as a hierarchy of three elements, which are fixed time consumption per build
operation, the total layer dependent time consumption and the total build time needed for the deposition of part geometry approximated by the voxels. Based on the build time estimation model, the energy consumption and cost estimation models were derived. The percentage errors of the time estimation for building a single bearing block and a turbine wheel were 1.03% and 8.71%, respectively.

Artificial-neural-network (ANN) techniques have also been used in build time estimation. Munguia et al. designed an ANN based model for SLS time estimation with the error rates ranging from 1% to 10%. This ANN model uses three parameters in the input layer, which are part height, part and bounding box volumes. The percentage estimation error was compared with that of the model developed by Ruffo et al., indicating that the average percentage error has been significantly reduced from 14.98% to 2.80%.

Di Angelo and Di Stefano also developed an ANN-based time estimator which only considers geometric features (e.g. prototype’s volume and height, layer thickness, total length of each layer’s contour and the number of repositioning movements) as the driving factors. Therefore, the estimator can be applied to a wide range of AM processes including FDM, three-dimensional printing (3DP), SLA, SLS and LOM. The estimation errors for FDM and 3DP were 11.45% and 12.21%, respectively. Although the model has shown good performance in predicting build times for different AM processes, complicated calculations, such as analysing the number of repositioning movements and calculating total length of the contours, are required.

From the above identified research, it is noted that, except for Di Angelo and Di Stefano’s estimation model, each of the developed models is only valid for one specific AM process. These models involve a large number of process parameters, and the parameters affecting build times vary depending on the AM processes used. For commercial software, the software packages that contain the functionality of build time estimation are sold in bundles with the AM systems. The typical examples are Cura and CatalystEX. Cura, which is integrated with the Ultimaker B.V. system and is able to predict the build
times of the components to be printed. The CatalystEX® software developed by Stratasys Inc. is equipped on all Stratasys Dimension FDM systems for preparation and control of printing jobs such as determination of part orientation, time estimation and layout of parts.

3 The method for developing a new build time estimation algorithm for FFF

The review documented in section 2 identifies the existing approaches for build time estimation. These estimators were based on the microanalysis of timing, using complex equations to describe the AM processes in detail. This estimation algorithm employs a macro-analysis approach, focusing on simple geometry parameters of the part to be built. The method is described below in 4 key stages (A01 – A04) as illustrated in Figure 1:

(1) Development of an analytical model (presented in section 4). An analytical analysis was first carried out to theoretically analyse the influential parameters. The analytical model was also used to accurately calculate build times for the experiments in the next three steps.

(2) Selection and determination of influential parameters (section 5). A test part was designed and the initial test was conducted, identifying and determining the significant parameters that were to be used in the build time estimation algorithm.

(3) Development of the new build time estimation algorithm (section 6). Four test parts with varying combinations of features were designed and a fractional factorial design strategy was employed to design a series of experiments. The statistical analysis techniques, namely multi-factor regression analysis and analysis of variance (ANOVA) were used iteratively to develop the new estimation algorithm.
(4) **Evaluation and validation of the developed algorithm** (section 7). Three test parts with specific features and part volumes, combined with the *t*-tests technique were used to evaluate and validate the developed algorithm. A real engineering part was printed to further test the algorithm validity.

**Figure 1 – The method for developing the build time estimation algorithm**

**4 Development of the analytical model**

This section provides details on the development of the FFF analytical model. The parameters are divided into process and geometry parameters, which were then used in the analytical model development.
4.1 Process and geometry parameters

Build time ($T_a$) is defined as the amount of time that is required to fabricate a single or a group of parts in FFF. The estimation of build time involves a number of parameters to be taken into consideration. These parameters can be split into process parameters and geometry parameters.

- Geometry parameters are the primary variables and they have direct effect on build times no matter what AM process is used.
- Process parameters are the controllable factors, and changing them can lead to the increase/decrease in build times. For example, increasing printing speed directly results in the reduction in build time.

However, it has been reported that the change of process parameters affects the output quality of the printed parts, such as surface quality, dimensional accuracy and tensile strength. The purpose of predicting build times is to identify the appropriate operation sequence which requires the least amount of build time. Despite the fact that changing the process parameters will most likely lead to the increase/decrease in build times, the aforementioned purpose cannot be achieved. This is because increasing or decreasing any or all of the speeds and accelerations/decelerations, affects the entire FFF process resulting in the increase or decrease in build times for producing the prototypes, respectively. Therefore, the process parameters were kept constant during the development of the estimation algorithm. The process parameters are summarised in Table 1, which will be used in the development of the analytical model in section 4.2.

4.2 The FFF analytical model

Assuming that a part is sliced into $N$ layers ($N = \lceil H/h \rceil$ and $\lceil \rceil$ represents the round up to the next integer number, $H$ is the part height and $h$ is the layer thickness), the overall build time of producing the part can be described as
where $T_{bed}$ is the time for warming up the bed to the material glass transition temperature ($T_g$) at which point the part stops warping; $T_{heater}$ is the time used in turning on the heater for extruding material; $T_n$ is the time used in printing the $n^{th}$ layer, $n \in [1, N]$. $T_{setup}$ is the machine set-up time, which involves retreating and relocating of the deposition nozzle when switching from CNC machining to FFF. $T_{setup}$ can be considered to be constant. Based on the practical printing experience, a uniform layer thickness (such as 0.2, 0.25 and 0.3mm) can be used to print the entire part, i.e. $h' = h$. The FFF process is stable and the part quality is repeatable when using a uniform printing speed (e.g. $V_{pr} = V_{pr}' = V_{shell\_out} = V_{shell\_in} = 60\text{mm/s}$). For each layer, the build time $T_n$ is divided into two parts, namely,

Equation 2

$$T_n = T_{dep\_n} + T_{idle\_n}$$

where, $T_{dep\_n}$ is the deposition time for the $n^{th}$ layer; $T_{idle\_n}$ is the idle time for the $n^{th}$ layer. Idle time includes deposition head repositioning time in the XY plane and Z axis ($T_{rep\_n\_xy}$ and $T_{rep\_n\_z}$), which can be calculated using Equation 3 below

Equation 3

$$T_{idle\_n} = T_{rep\_n\_xy} + T_{rep\_n\_z} = \frac{h}{V_z} + \sum_{j=1}^{J} \left( \frac{S_{rep\_j\_xy}}{V_{xy}} - \frac{V_{xy}}{A_{xy}} \right)$$

where, $S_{rep\_j\_xy}$ is the $j^{th}$ ($j \in [1, J]$) repositioning displacement (unit: mm) before depositing the $j^{th}$ continuous deposition path.

Deposition time ($T_{dep}$) is the time when the material is being extruded. Thus, the time used in depositing the $n^{th}$ layer is expressed in Equation 4:
Equation 4

\[ T_{\text{dep}_n} = \sum_{k=1}^{K} \left( \frac{2 \times L_{\text{ret}_k}}{V_{\text{ret}}} + \frac{S_{\text{pr}_k}}{V_{\text{pr}}} - \frac{V_{\text{pr}}}{A_{\text{xy}}} + T_{\text{delay}} \right) \]

where, \( S_{\text{pr}_k} \) is the length of the \( k^{\text{th}} \) \((k \in [1, K])\) continuous deposition path; \( L_{\text{ret}_k} \) is the length of the filament retracted before depositing the \( k^{\text{th}} \) deposition path. \( T_{\text{delay}} \) is the delay time before depositing material on each individual continuous path.

Based on the analysis outlined in the Equations 1 to 5, a full representation of the build time for a single part is derived, as expressed below. It should be noted that, this analytical model can only be used under the circumstances where the CAD model is sliced into a number of layers and the tool paths have been generated.

\[ T_a = T_{\text{bed}} + T_{\text{heater}} + T_{\text{setup}} + \sum_{i=1}^{I} \left[ \sum_{j=1}^{J} \left( \frac{S_{\text{rep}_{i,j_{xy}}}}{V_{xy}} - \frac{V_{xy}}{A_{xy}} \right) + \sum_{k=1}^{K} \left( \frac{2 \times L_{\text{ret}_k}}{V_{\text{ret}}} + \frac{S_{\text{pr}_k}}{V_{\text{pr}}} - \frac{V_{\text{pr}}}{A_{\text{xy}}} + T_{\text{delay}} \right) + \frac{h}{V_Z} \right] \]

5 Selection and determination of influential parameters

In this section, the process parameters to be investigated in the experiments are selected. This consists of initial selection of the parameters, determination of the parameters to be included in the estimation algorithm and the introduction of intermittent factor.

5.1 Initial selection of the parameters

Based on the analytical model above, the following statements are made:
• Calculation of the build time using the analytical approach (Equation 5) is generally not practical at the operation sequencing stage in which only CAD models or 2D drawings are given.

• Total length of deposition path \( (S_{pr}) \) primarily determines build times when certain printing speed and acceleration/deceleration are applied. Therefore, part volume \( (V) \) is considered as one of the major parameters that directly contribute to the total amount of build time.

• Hatch spacing \( (\lambda) \) is represented in Equation 5 by the use of \( S_{pr} \). A high value of hatch spacing indicates low density of the part (i.e. the part is more porous), which in turn reduces the total length of the deposition path \( (S_{pr}) \). As a result, part density \( (\rho) \) is introduced in the build time estimation algorithm to represent \( \lambda \) and \( S_{pr} \). Density is also defined as: density = 100% - part porosity.

• Part height \( (H) \) has a direct effect on build time. Different heights of the part resulting from the change of part orientations can result in different build times.

• Reducing the length of repositioning tool path \( (S_{rep}) \) could lead to decreases in machine idle time \( (T_{idle}) \). For each time the deposition head repositions, filament retraction and print delay \( (T_{delay}) \) are required, resulting in increased build time. The reasons that cause the head to reposition are \((i)\) start printing next layer; and \((ii)\) certain areas do not require material, such as printing pockets. Hence, the importance of head repositioning and the resulting idle time is investigated in section 5.2 in order to decide whether or not to include this parameter in the estimation algorithm.

5.2 Determination of the parameters

According to the statements made in section 5.1, test part A was designed (as shown in Figure 2) to evaluate the importance of deposition head repositioning time (i.e. idle time). The \( 2^4 \) full factorial design of experiments (DoE) strategy was used. Five sets of parts with four different sizes of through pockets were designed. Producing rectangular blocks with pockets requires repositioning the deposition head repeatedly and frequently since the pockets do not need material. Every time the head travels across the
pocket, it can be seen as a repositioning action. In order to avoid the effects caused by the varying volumes and heights, all parts in each set had the same volume and height but different pocket sizes as compared to the other parts in the same set. A density of 25% was also applied to all the parts.

![Test part A](image)

Figure 2 – Test parts A

The build times were calculated by using the developed analytical model (Equation 5), which can be considered as the actual build times. The results (i.e. build times) were analysed using ANOVA, revealing that deposition head repositioning is a significant parameter in relation to total build times. The ANOVA results are shown in Table 2.

</table>
Due to $F_{credit} = 3.49 < F_{statistic} = 316.82$, significant difference in build times has been identified while changing the length of repositioning tool path. The test demonstrates that build time is not only dependent on the total volume of the part, but also the distribution of material. Hence, length of repositioning tool path should be included in the build time estimation algorithm.

5.3 Intermittent factor

As stated in section 1, the parameters in the estimation algorithm should be obtainable from the CAD model and/or 2D drawings. However, from the test presented above, the distance travelled in repositioning and the number of times for repositioning cannot be obtained from the CAD model and/or drawings, which also depends on the part geometry and the slicing strategy employed. A term entitled intermittent factor ($I$) is therefore proposed to reflect the influence of the above two variables against total build time. A high intermittent factor implies that a significant amount of time is used in repositioning the deposition head and other relevant actions such as filament retraction and print delay. Assume that a feature (e.g. feature $A$) is sliced into a number of layers where discrete deposition areas exist. The intermittent factor can be calculated as the product of the ratio of discrete areas and STL boundary areas, and the ratio of feature $A$’s height and the height of outer feature that contains feature $A$.

To this end, part volume ($V$), part density ($\rho$), part height ($H$) and intermittent factor ($I$) were selected and defined to be investigated in the experiments for developing the estimation algorithm in sections 6 and 7. Among these four parameters, part volume and height can be directly obtained from the CAD model and/or drawings; part density is specified by the operator; and the intermittent factor can be calculated based on the dimensions of the features.
6 Developing the new build time estimation algorithm for FFF

This section details the development of the new build time estimation algorithm consisting of Test part design; Design of experiments for the estimation algorithm development; and Experimental results, analysis and discussions.

6.1 Test part designs

There have already been several existing test parts for AM systems, but most of these parts were designed for accuracy evaluation only. As introduced in section 1, the estimation algorithm will be used in process planning for the iAtractive process. Given that the iAtractive process is currently used to manufacture prismatic parts and the majority of engineering parts are prismatic or cylindrical in nature, the designs of the test parts (part B, C, D and E in Figure 3) include the full family of the prismatic features, namely, boss, pocket, slot, step, hole and planar face. Each of these test parts contains at least four different features and one combination of features, such as the combination of a step and a hole in test part B, and the combination of a boss and a pocket in test part C.

(a) Test part B

(b) Test part C
6.2 Design of experiments for the estimation algorithm development

Given that the four parameters are multi-level variables and their outcome effects are not linearly related, four levels were chosen to apply to part volume, height and density for each test part design. As the aim of the experiments was to develop the estimation algorithm rather than identify the influence of important factors only, the Taguchi method was not considered to be appropriate. Another standard approach for DoE is to use the full factorial method. However, this method is only acceptable and feasible when a few (usually no more than three) factors are to be explored. For predicting build times, the more experimental data obtained the more accurate the prediction results. As a result, the levels of the parameters need to cover a wide range of values. For instance, it is better to investigate the influences caused by both small and large part volumes, and other volumes in between. Based on these reasons, the four test parts were increased in scale by a factor of 1.2, 1.4 and 1.6, by which the part volume, height vary accordingly. Four levels of part density, namely 25%, 50%, 75% and 100% were used for each part volume and height variables. As a result, 64 experimental runs were required. The print settings are shown in Figure 4 below.

‡ Small volume < 50cm³, medium volume 50-100cm³, and large volume > 100cm³
6.3 Experimental results, analysis and discussions

To obtain the estimation algorithm, regression analysis and ANOVA was carried out iteratively. The errors were analysed by comparing the actual and the predicted build times to identify the importance of the interactions among the four control factors. By feeding back the error analysis, the final estimation algorithm was obtained, where unimportant interactions were removed. The actual build time \( T_a \) and the estimated build time \( T_a^* \) can be depicted in Equations 6 and 7, respectively.

$$ T_a = f_1(V, H, \rho, I) + f_2(V, H, \rho, I) + \cdots + \sum_{p=1}^{P} f_p(V, H, \rho, I) + T_{\text{bed}} + T_{\text{heater}} + T_{\text{setup}} $$
Equation 7

\[ T_a^* = C + f_1^*(V, H, \rho, I) + f_2^*(V, H, \rho, I) + \cdots + \sum_{q=1}^{Q} f_q^*(V, H, \rho, I) + T_{\text{bed}} + T_{\text{heater}} + T_{\text{setup}} \]

where, \( f_i \) and \( f_i^* \) are the functions related to part volume, height, density and intermittent factor in the analytical (actual) and the estimation algorithm, respectively. \( C \) is the intercept. Thus, the deviation (\( \zeta_m \)) for each individual experiment can be expressed using Equation 8.

Equation 8

\[ \zeta_m = |T_{\text{total},m} - T_{\text{total},m}^*| \]

where \( T_{\text{total},m} \) is the actual build time in experiment \( m \) and \( T_{\text{total},m}^* \) is the estimated build time in experiment \( m \). The root mean square of the deviation (\( \text{RMS}_\zeta \)) and each function (\( \text{RMS}_{f_i} \)) in the estimation algorithm can be calculated using Equations 9 and 10, where, \( m \) denotes experiment number \( m \).

Equation 9

\[ \text{RMS}_\zeta = \sqrt{\frac{\sum_{m=1}^{M} \zeta_m}{M}} \]

Equation 10

\[ \text{RMS}_{f_i} = \sqrt{\frac{\sum_{m=1}^{M} f_{i,m}}{M}} \]

Given that producing a mid-range sized prototype (i.e. \( 1.25 \times 10^2 \) cm\(^3\)) requires up to 7 hours, the acceptable deviation between the actual and estimated build times was set to be five minutes. Therefore, for those \( \text{RMS}_{f_i} \) that were one or more orders of magnitude greater than \( \text{RMS}_\zeta \), the corresponding functions were kept in the next run of the estimation algorithm development process. Other functions were removed from the algorithm. After five iterations, the final build time estimation algorithm was obtained as depicted in Equation 11.
Equation 11  \[ T_a = 168.33 + 23.56V + 9.44H + 160.19V\rho + 78.17HI + T_{\text{bed}} + T_{\text{tevar}} + T_{\text{setup}} + \varepsilon \]

where, \( \varepsilon \) is the uncertainty in the actual experiments.

The selected analysis results are shown in Table 3, which were obtained by fitting the estimation algorithm as depicted in Equation 11. Since the \( P \)-values of part volume, the interaction of volume and density, and the interaction of height and intermittent factor are significantly smaller than the threshold value of 5% in the analysis, they are of primary significance. Among them, the interaction of volume and density is the most significant factor, followed by part volume. With respect to the regression confidence \( (R^2) \), the adjusted regression confidence \([ (R^2)_{\text{adj}} ]\) and the difference between them indicates that the regression model is satisfactory.

The residual analysis was carried out for checking the adequacy of the developed estimation algorithm. Figure 5 is the normal probability plot of the standardised residuals of the regression model (i.e. FFF build time estimation algorithm). It is considered as satisfactory due to the standardised residuals that are evenly distributed along the straight line. Figure 6 shows the distribution of the standardised residuals.
versus the experiment numbers. No distinct pattern has been observed, revealing that the current model is appropriate and no further factors are required for describing the relationship between the input factors and the estimated times. Approximately 98.4% of the standardised residuals fall in the interval (-2, +2), demonstrating that the errors are normally distributed. Nevertheless, it should also be noted that there are two points that are outside the interval. The standardised residual of one of the points is 2.01, which can still be considered as normal, but another standardised residual of 3.02 indicates the presence of an outlier. Thus, the parameters in the corresponding influential observation (experiment number 45) were traced back and the distance of the point from the average of all the points in the data set was recalculated. The results show that the outlier does not have a dramatic impact on the regression model. Figure 7 also supports this statement, which plots the errors curve showing that the error of 2.2% in experiment 45 is acceptable. Due to an unknown reason that caused the high-standardised residual, more tests were required to validate and evaluate the performance of the model, which will be presented in section 7.

![Normal Probability Plot](image)

**Figure 5 – Normal probability plot of standardised residuals**
It is noted that the errors tend to increase while the part volume is small, as identified in Figure 7. While the four test parts were not scaled up (experiment 1-4, 17-20, 33-36 and 49-52), the errors are relatively larger than the errors in other experiments. In addition, the original volumes of test parts D and F are small (less than 50 cm$^3$). As a result, the errors do not decrease significantly while the parts were scaled up 1.2 times. An exact reason cannot be provided, however for small and medium parts where the volume does not exceed 100 cm$^3$, even though the number of repositioning and filament retraction times are kept unchanged, the length of the repositioning tool path is significantly shorter than that of the larger volume parts, while the intermittent factors are identical. This may lead to an increase in estimation error. Furthermore, it is worth mentioning that errors can be simply reduced to lower than 1% by expanding Equation 11 with additional factors (e.g. adding interactions between $V$, $H$, $\rho$ and $I$, as shown in Equation 12 as an example).
Equation 12

\[ T_a^* = 51.32 + 26.71V + 8.62H + 160.19VH + 0.07VH + 69.83HI + 0.10H^2 + T_{\text{tool}} + T_{\text{heater}} + T_{\text{setup}} + \epsilon^* \]

7 Evaluation and validation of the new build time estimation algorithm

Upon obtaining positive results from the previous experiments, two case studies were conducted for the evaluation and validation of the build time estimation algorithm, and are detailed below.

7.1 Case studies I

7.1.1 Design of experiments for cast study I

The test parts designed in this section include various features, as shown in Figure 8, and more importantly, fabricating these features requires varying length of repositioning tool paths and differing number of repositioning and filament retraction times. Test parts F and H were modified based on the
parts designed by Kechagias et al.\textsuperscript{30} and Zhou et al.\textsuperscript{45}, respectively. Test part H contains nine features including planar face, boss, pocket, sphere and chamfer.

![Test part F](a)

![Test part G](b)

![Test part H](c)

Figure 8 – Test parts F, G and H

It was found that the majority of the estimation inaccuracy lies in producing parts with a volume of less than 50 cm$^3$. Therefore, the volumes of test parts G and H were specifically designed to be less than 50 cm$^3$. Subsequently the three original test parts were scaled up 1.2, 1.4 and 1.6 times, generating 12 test parts with differing part volumes and heights. Due to the interaction of volume and porosity that is the most significant factor, 25%, 50%, 75% and 100% levels of porosity were applied to these 12 test parts. As a result, a total of 48 test parts were defined.
7.1.2 Experimental results and analysis for case study I

Table 4 presents the results obtained in the experimental runs 17-32. The errors between the estimated and the actual build times are also presented. It is observed that the errors for the part volume of 45cm$^3$ could be up to -6.73%, whereas the largest error is only 0.75% for the part volume of 187.11cm$^3$. With the increase in part volume, the mean error gradually reduces from 3.44% to 0.36%.

The percentage errors between the predicted and actual times are plotted in Figure 9. The average error is 6.7%, the best results were obtained in the experimental runs 17-32 and there is no obvious fluctuation (less than 13.5% error) in the experimental runs 1-16 and 33-48. As the estimation algorithm (Equation 11) only has four factors rather than six (Equation 12), it is not as sensitive as Equation 12 in terms of prediction accuracy when a large number of repositioning movements are required for building a part. The test parts in the experiments 17-32 (test part G and variations) have a low intermittent factor (less than 0.2), indicating the short length of repositioning tool paths, relatively low number of repositioning and filament retraction times, as well as a short resulting delay time during production. Thus, the resulting errors were reduced. In other words, the developed estimation algorithm has better performance for parts with a low intermittent factor (< 0.2). The predicted times tend to be longer than the actual times while the algorithm is applied to parts with a high intermittent factor (> 0.5).

</table>
In order to evaluate the algorithm, a statistical method, namely, $t$-tests was used to analyse the results, identifying whether significant difference exists between the estimated and actual build times. Paired $t$-tests were carried out for all the test parts at a 95% confidence interval for the analysis of the differences between the estimated and actual times. The selected results are listed in Table 5, where $t$-stat is $0.75 < t$ two-tail critical $= 2.01$ ($\alpha = 0.05$). Thus, it can be concluded that the build time estimation algorithm does not yield significantly different results when compared with the actual times.

7.2 Case studies II

An engineering part shown in Figure 10 was used to further test the validity of the developed estimation algorithm. The volume and height of the part are $26.67 \times 10^3$ mm$^3$ and 31 mm, respectively. As it is an engineering part, the part density is specified as 100% solid. Based on the dimensions, the intermittent factor can be calculated, which is 0.575. The estimated results are listed in Table 6, and the percentage error is 8.3%, demonstrating the efficacy of this new proposed algorithm.

7.3 Discussion on the new build time estimation algorithm

Based on the case studies and analysis, it can be identified that the developed estimation algorithm is able to predict build times and the predicted results do not have significant difference to the actual times. In comparison to other estimators\cite{28, 30, 31, 35, 38}, this estimation algorithm offers a time-saving method, which only requires the part dimensions, i.e. 2D drawings. This eliminates considerable time used in slicing CAD models and post-processing them for build time calculation.

Whilst the advantages of the proposed method have been documented and described, there are a number of other issues, which need to be addressed. Firstly, the algorithm shows advantages only for parts in
which all the features involved are prismatic. However, it is currently not suitable for parts with sculptured free-form surfaces because the intermittent factor cannot precisely represent properties of such structures. Although it is possible to approximate shapes and volumes contained by free-form surfaces into a large number of prisms, Campbell et al.\textsuperscript{31} pointed out that estimated build times might still remain inaccurate. The major advantage of this algorithm is high efficiency, which is able to estimate build times based on the part dimensions in 2D drawings. As such, the algorithm only includes the four most significant factors documented in section 5. In the future, efforts will be made to enhance the functionality and accuracy of the algorithm for precisely predicting times for sculptured surfaces. A possible solution is to employ a correction factor used by Pham and Wang\textsuperscript{24}, which partly depends on the ratio of the part volume to the volume of a bounding box around the STL file. By introducing this factor, more attributes including geometry complexity, wall thickness and the number of parts to be fabricated in one single set-up can be taken into consideration.

Furthermore, the estimation algorithm is developed based on the deposition of polylactic acid (PLA) and the layer thickness of 0.25mm. PLA is now one of the most widely used materials for FFF. Changing material such as acrylonitrile butadiene styrene (ABS) will affect build time and the firmware of the FFF system will automatically adjust the relevant speeds accordingly, such as printing and travelling speeds of the deposition head, to ensure correct printing. Printing ABS is more time intensive when compared to PLA because the deposition head needs to go slower to allow for heat dissipation, requiring more time to cool the part to prevent overheating and lose of printing details. The printing temperatures for PLA and ABS are 200°C and 240-260°C, respectively. The main difference between printing PLA and ABS is welding. PLA creates an extremely strong weld to itself so that cooling fans can be used to accelerate the cooling process. In contrast, ABS bonds to itself very weakly, therefore adding cooling fans makes this worse and can initiate cracking. The relatively slow printing of ABS is also due to its $T_g$ being higher than PLA. Although the method proposed in section 3 can still be used to develop a new estimation algorithm
when material, layer thickness and other parameters are changed, it would still be better to introduce an adjustment factor into the current developed algorithm, which is able to adjust estimated results based on different materials and layer thicknesses. Additionally, Equation 5 in section 4.2 can always be used to accurately calculate build times for different materials in the circumstances where the CAD model is sliced into layers and the tool paths are generated.

For different types of system, namely Cartesian and Delta systems, the key difference between them lies in the motion control mechanism, which can affect the dimensional accuracies of the printed parts. For low printing speeds (i.e. < 80mm/s), both Cartesian and Delta systems are able to fabricate parts, achieving the same (or very close) dimensional accuracies. However, for high printing speeds (i.e. > 80mm/s), the Delta system usually shows better dimensional accuracy due to the low rotatory inertia of the motors for motion control and the low accumulative error in the XY plane. With respect to the build time for printing a part, the printing speed is defined by a user and then coded in a programme called G-Code, which is similar to NC codes for CNC machines. Thus, as long as the same G-Code is used, the build times will be the same no matter which system the part is printed by. In this study, the printing speed of 60mm/s is used, which is the most stable and widely used speed for Cartesian FDM machines, such as Stratasys FDM<sup>40</sup>. Further to the filament diameter, it barely affects actual build times. This is because, for printing the same object, the build time is dependent on printing and travelling speeds of the deposition head. Based on the given speeds, the firmware calculates feedrate of the filament that is fed into the liquefier chamber. The feedrates for filament of ϕ1.75 or 3mm may be different, however, the volumes of the semi-melted material extruded from the nozzle per unit time are the same.

7.4 Limitations and constraints in the development of the estimation algorithm

This subsection summarises the limitations of the estimation algorithm and the constraints that led to the limitations during the algorithm development process.
• Relatively simple features. The estimation algorithm has been developed to predict FFF build times for prismatic parts in the context of hybrid manufacture. While the iAtrative process\textsuperscript{13} is currently aimed at producing difficult-to-cut (internal structures) prismatic parts, the future trend is to realise high precision manufacture of both internal features and sculptured free-form surfaces.

• Few factors considered. Only four factors, i.e. volume, height, density and intermittent factor, are taken into consideration due to the efficiency consideration in process planning for the iAtractive process. Process planning requires fast and efficient time estimation based on 2D drawings (feature dimensions), which are the most accessible geometrical information for the iAtractive process. This requirement has imposed a constraint to the estimation algorithm. Adopting existing time estimation methods presented in the papers\textsuperscript{26-30, 35, 38} is not viable since these methods need to further process the given CAD model (i.e. slicing it into layers and generating tool paths for the deposition head). Due to the limited number of factors included in the authors’ estimation algorithm, it is currently not able to provide high estimation accuracy for sculptured free-form surfaces. An effective approach to improving the accuracy, as identified in Equation 12, is to increase the number of factors in the algorithm.

• Limited choices of FFF process parameters. The estimation algorithm was investigated in the condition where the material, layer thickness, printing speeds and infill patterns were set as PLA, 0.25 mm, 60 mm/s and rectilinear, respectively, which are the FFF recommended settings\textsuperscript{46}. This limitation has constrained a user from defining his/her preferred printing parameters and values for customised products.

• Diminished estimation accuracy in predicting times for printing an array of parts (multiple objects). Parts are sometimes preferred to be fabricated simultaneously in a single FFF operation, in which case a large number of parts are arranged on a build platform with certain distances (defined by the
user) with each other. This leads to an increase in the repositioning displacement \( S_{rep_{j,xy}} \) (see Equation 5), which further results in the increased proportion of time in repositioning the deposition head from one-part cross section to another. The predicted build time is likely to be less accurate due to the poor predictions of the repositioning time.

8 Conclusions and future work

In this paper, a new build time estimation algorithm for the FFF process under the context of hybrid manufacturing has been developed. The input for the algorithm can be directly obtained from the part dimensions/drawings, providing a new, accurate and efficient approach to time estimation. The method for developing the algorithm was described and consisted of four major stages as described in Figure 1. The analytical model was first created to analyse process and geometry parameters. This analytical model was then used in the later stages to accurately calculate build times. The selection of influential parameters, the estimation algorithm development and evaluation were carried out in sequence. A robust experimental approach was used consisting of a design of experiments approach, and the results were statistically analysed and discussed at each stage. Part volume, height, porosity and intermittent factor together with their interactions have been identified as the significant parameters that affect build times. The estimation algorithm is capable of predicting build times with an average error of 6.7%, the maximum error of 13.5% on the total build time, and 80% of this error falls within an 8% deviation. The statistical analysis indicates that no significant difference was found between the estimated and actual build times. In addition, deviation is likely to increase for parts with a large intermittent factor (> 0.5) or volume of less than 50cm³. This clearly demonstrates the significance of this work and its influence on the emerging domain of hybrid manufacture. The build time estimation algorithm differs from existing methods by being able to directly predict build times based on part dimensions without the need to further process the CAD model or run complex algorithms. This provides a more fluid and robust method to
predict build times. Beneficiaries of this new algorithm will be manufacturing engineers who fabricate functional parts using AM or hybrid processes, and designers who build prototypes to evaluate and validate designs.

Future work will focus on implementation of this new algorithm for build time estimation on a wide range of AM methods particularly aligned to the combination of additive and subtractive manufacturing technologies. Further enhancements to the functionality of the algorithm to provide accurate prediction of build times for free-form complex surfaces and components will be made. This may require an extra parameter to compensate for the intermittent factor to reflect geometry complexity and changes in part volume.
