ABSTRACT

Background Injury risk in youth rugby has received a much attention, highlighting the importance of establishing evidence-based injury reduction strategies.

Aim To determine the efficacy of a movement control exercise programme in reducing injuries in youth rugby players, and to investigate the effect of programme dose on injury measures.

Methods In a cluster-randomised controlled trial, forty independent schools (118 teams, 3,188 players aged 14-18 years) were allocated to receive either the intervention or a reference programme, both of which were to be delivered by school coaches. The intervention comprised balance training, whole-body resistance training, plyometric training, and controlled rehearsal of landing and cutting manoeuvres. Time-loss (>24 hours) injuries arising from school rugby matches were recorded by coaches and medical staff.

Results 441 time-loss match injuries (intervention-233; control-208) were reported across 15,938 match exposure-hours (intervention-9,083; control-6,855). Intention-to-treat results indicated unclear effects of trial arm on overall match injury incidence (Rate Ratio (RR)=0.85, 90% CL: 0.61-1.17), although clear reductions were evident in the intervention arm for concussion incidence (RR=0.71, 0.48-1.05). When trial arm comparisons were limited to teams who had completed 3 or more weekly programme sessions on average, clear reductions in overall match injury incidence (RR=0.28, 0.14-0.51) and concussion incidence (RR=0.41, 0.17-0.99) were noted in the intervention group.

Conclusion A preventive movement control exercise programme can reduce match injury outcomes, including concussion, in schoolboy rugby players when compared with a standardised control exercise programme, although to realise the greatest effects players should complete the programme at least three times per week.
INTRODUCTION

The injury risk in youth rugby has received attention in the mainstream public and sports medicine literature,[1,2] and has prioritised the formulation of appropriate preventive measures.[3] Musculoskeletal injuries and concussion are prominent reasons for time-loss from sport for adolescent rugby players,[4,5] and significant youth sports injuries in general have been implicated in long-term disability and compromised quality of later life.[6,7] Conditioning the musculoskeletal system to tolerate external forces, through enhancing strength and movement control, has been advocated as means of reducing musculoskeletal injury risk, as indicated by a growing evidence base that supports using multifaceted preventive exercise programmes to reduce musculoskeletal injury risk across male sports like basketball,[8] and soccer.[9-11] Moreover, cross-sectional associations between neck strength measures with concussion risk in young athletes invite the possibility that interventions to enhance neck strength may reduce concussion risk.[12] The injury patterns in rugby differ from other team sports, owing to a greater frequency of concussion, upper body, and contact-related injuries,[13,14] and so it is uncertain if introducing a targeted exercise programme can reduce musculoskeletal injuries and/or concussion in youth rugby players.

The efficacy of preventive exercise programmes is dependent upon several factors; of which the frequency of programme use (i.e. dose) may be one such factor.[15] Dose-response relationships have typically been identified between programme use and reductions in knee ligament injury incidence in female sportspeople.[16,17] Assessing the effects of programme dose can be useful in reinforcing the outcomes of intervention research and informing subsequent implementation attempts.[18]

The aims of this study were to assess the efficacy of a pre-activity movement control exercise intervention to reduce the incidence and burden of rugby-related injuries in a schoolboy population, and to assess the influences of programme dose and compliance on injury outcomes.
METHODS

Study Design and Recruitment

A cluster-randomised controlled trial was conducted across independent school rugby teams over 1 playing season (August-December 2015). Study design was in accordance with the CONSORT statement,[19] and the trial was registered before recruitment (Trial registration number: ISRCTN13422001). Study procedures were approved by the Research Ethics Approval Committee for Health (REACH) at the University of Bath.

Each school was treated as a cluster, within which under-15 (U15), under-16 (U16), and under-18 (U18) teams were allocated to the same trial arm. A-priori sample size calculations were undertaken,[20] incorporating injury data collected from a previous study on injuries in schoolboy rugby players.[5] To discern a 30% reduction in match injury incidence at 80% statistical power, 13 schools per trial arm were required. Seven additional schools were recruited in each trial arm to account for attrition, yielding a target sample of 40 schools.

Schools deemed eligible to participate had on-site access to physiotherapists or nurses who would treat all rugby-related injuries. Two-hundred and twenty schools were identified and sequentially contacted in randomised groups of 60 through trial invitation letters; emails, and direct telephone calls to senior members of the sport and rugby programmes until 40 schools had provided written informed consent from a member of the senior management team to participate in the trial. Schools were randomly allocated to the intervention or control groups on a 1:1 basis. The randomisation process for both recruitment and allocation was completed independently of the research team. Schools were briefed that they would receive an exercise programme to be delivered by the coaches to their U15, U16, and U18 teams, but were blinded to their trial arm allocation. All U15, U16, or U18 players who participated in training or match-play at the school were eligible to participate in the trial. Coach consent (in loco parentis), player assent, and opportunity for parental opt-out (via school-parent mailing lists) were sought.
Coaches attended a pre-study workshop (typically 1 hour duration) led by the research team at each school (June-July 2015), at which they were introduced to either the intervention or control exercise programme and data collection materials, in addition to being provided with a practical demonstration of the programme. The practical demonstration of the programme entailed coaches observing a research team member leading a group of youth rugby players (U15, U16, or U18) through a session. Coaches across both trial arms received identically formatted data collection and programme materials (except for exercises). Programme materials included a filmed demonstration of the exercises (as a DVD), laminated cue cards (images and key coaching cues for each exercise), and a booklet detailing how to complete individual exercises. A further meeting was arranged at all schools during pre-season for members of the research team to collect informed assent and baseline anthropometric information (standing height, seated height, body mass) from all players involved in the trial.

**The Exercise Programmes being trialled**

The process of devising the intervention and control exercise programmes have been reported elsewhere.[21] Both programmes comprised 4 phases, with progressions occurring via increased difficulty and repetition volume of exercises. Phase 1 was devised for the pre-season period (typically 1-2 weeks duration). Both programmes progressed to phase 2 upon the school term commencing in September 2015, with two further planned phase progressions occurring every 4-weeks until the end of the study in December. This timing enabled players to master the exercises before being introduced to a more advanced phase. Progression of the exercises was undertaken at the team-level, with all players within the same age group teams completing the same exercises at the same time. Phase difficulty was offset by age group (i.e., phase 3 of the U15 programme was similar in difficulty to phases 2 and 1 of the U16 and U18 programmes, respectively) to maintain a sufficient stimulus for players at an appropriate level. Both programmes were intended to take place during the first 20 minutes of each pitch-based training session and match warm-up, and coaches in charge of each team acted as delivery agents. Coaches were instructed to use
the programme materials, particularly the laminated cue cards during sessions, to assess movement execution in relation to the specified cues for each exercise, and to identify movements that could be improved.

The exercise programme allocated to teams in the intervention group integrated balance/perturbation training, resistance training, plyometric training, and controlled rehearsal of sport-specific landing and cutting manoeuvres with verbal feedback and reinforcement of technique from the coach. The exercise programme allocated to the control cohort was derived from currently regarded best practice within schoolboy rugby, and featured a running-based warm-up, dynamic stretching, controlled wrestling, mobility, and speed / change of direction-related drills (without the specific feedback instructions given in the intervention programme). The content within both the intervention and control programmes were categorised into 4 separate parts (Parts A, B, C, and D) to aid the structure of sessions and compliance reporting. A sample phase from the intervention exercise programme have been supplied for supplementary reference.

Data Collection

The definitions of a reportable injury (incurring a time-loss of more than 24 hours), match exposure, and training exposure (only pitch-based activities) were adapted from the consensus statement for injury definitions and data collection procedures in rugby union.[22] Coaches recorded training exposure (length of each training session in minutes, number of players attending training session), match exposure (match date, opponent name, list of players selected to play in each fixture) and programme compliance at each session (completion of programme parts A, B, C, and D) on weekly paper-based or electronic report forms. Programme compliance indicated the proportion of programme parts that were completed at the team level across all exposures. Coaches started the injury reports by logging the date that the injury occurred, the injured player’s trial ID and playing position, and the event leading directly to the injury. School medical staff recorded the injury location and a diagnosis when players visited for treatment. Logging the injury location and diagnosis
aligned with the first two levels of the Orchard Sports Injury Classification System (Version 10).[23] Coaches recorded the return-to-play date (date of full participation in training or match-play). A member of the research team visited schools periodically (2-3 week intervals) during the study period to retrieve completed report forms and to discuss study progress, but not to promote compliance or fidelity with using the programmes.

**Statistical Analyses**

Statistical analyses were undertaken with IBM SPSS Statistics (Version 22.0 for Windows, IBM Corporation, Armonk, NY, USA). Trial arm comparisons across baseline player characteristics (age, anthropometric characteristics, and maturity timing) were assessed using linear and logistic regression. The odds ratio generated from the logistic regression was converted to a proportion ratio to permit analysis via magnitude-based inference.[24] Intention-to-treat analyses compared injury measures between the trial arms for all teams that provided injury and exposure data, regardless of returning complete programme compliance or dose data. Trial arm comparisons were also undertaken on a per-protocol basis with teams that maintained a mean programme completion rate of 3 or more weekly sessions, which represented a threshold for optimal compliance based on previous findings.[25] The effects of intervention-only programme dose on injury were assessed by comparing injury measures between teams that maintained an average of 3 or more sessions per week with those who averaged completing the programmes less than 3 sessions per week. Overall match injury incidence (injuries/1000 player-hours) and burden (days lost/1000 player-hours) rates acted as dependent variables, with further stratification by injury location and event. All estimations were made using generalised linear modelling with a Poisson distribution, a log-linear link function, and offset for hours of exposure to generate rate ratios (RR) and 90% confidence limits (90% CL) for injury incidence and burden values. RR and 90% CL were assessed against pre-determined smallest worthwhile effects in injury outcome.[26] The smallest worthwhile effects favouring the intervention and favouring the control were given as RR=0.90 and RR=1.11, respectively.[27] Effects were
deemed clear if the percent likelihood that the true effect favoured the intervention (RR below 0.90) was greater than 25%, and the odds ratio between favouring the intervention and favouring the control was greater than 66 (i.e. if the likelihood of effect favouring the intervention was 25% and the likelihood of effect favouring the control was less than 0.5%), otherwise effects were deemed unclear. Effects were qualified against probabilistic terms from the following scale: <0.5%, most unlikely; 0.5-5%, very unlikely; 5-25%, unlikely; 25-75%, possibly; 75-95%, likely; 95-99.5%, very likely; >99.5%, most likely.[28]

RESULTS

From a target population of 220 potentially eligible schools that were contacted for recruitment, 40 schools (118 teams, 3,188 players aged 14-18 years) consented to participate in the trial and were randomly allocated to the intervention or control group (Figure 1). Nine schools and 35 teams dropped out of the trial, with data collected from 31 schools, 83 teams, and 2,452 players used for analysis (intervention, 17 schools, 44 teams, 1,325 players; control, 14 schools, 39 teams, 1,127 players). Comparisons of baseline player anthropometric characteristics between the trial arms are outlined in Table 1. Trivial differences were detected between the trial arms for mean player age, stature, body mass, or the distribution of players by maturity timing (Table 1).

Exposure, injury, and compliance

The intervention cohort (n=17 schools, 44 teams) accrued 37,346 exposure-hours (match, 9,083, training, 28,263), with the control cohort (n=14 schools, 39 teams) reporting 32,375 exposure-hours (match, 6,855, training, 25,520). The intervention cohort recorded 233 match injuries (totalling 6,499 days lost) and 58 training injuries (1,028 days lost), with the control cohort recording 208 match injuries (5,907 days lost) and 54 training injuries (1,150 days lost). Overall match and training injury incidence in the intervention cohort was 26/1000 hours (23-29) and 2/1000 hours (2-3), and in the control cohort was 30/1000 hours (27-34) and 2/1000 hours (2-3), respectively.
Summary injury and exposure results between the trial arms are outlined in table 2. Of 441 reported match injuries, 168 were sustained to the head/neck (intervention, 82, control, 86), 125 to the upper limb (intervention, 65, control, 60), 113 to the lower limb (intervention, 67, control, 46), and 35 to the trunk (intervention, 19, control, 16). Of 168 head/neck injuries, 105 were reported as concussion (intervention, 51, control, 54). Match concussion incidence in the intervention group was 6/1000 hours (4-7), and in the control group was 8 (6-10).

Complete compliance data was retrieved from 63 out of 83 teams (intervention, 32 teams; control, 31 teams). In teams who had provided complete compliance information, mean programme completion rate across both trial arms was close to twice per week (intervention, 1.9 sessions/week; control, 2.0 sessions/week). Twelve out of 63 teams maintained a mean weekly programme completion rate of 3 or more sessions (intervention, 7 teams; control, 5 teams). Compliance to the exercise programmes (proportion of programme parts that were completed) were 69% and 83% across the intervention and control arms, respectively.

0 **Intention-to-treat analyses**

Intention-to-treat analyses on the effect of trial arm (intervention, 17 schools, 44 teams; control, 14 schools, 39 teams) were unclear for overall match injuries (Incidence RR=0.85, 90% CL: 0.61-1.17; Burden RR=0.83, 0.58-1.18) (Figure 2). Effects were also unclear for contact-related injuries (Incidence RR=0.85, 0.60-1.19; Burden RR=0.88, 0.60-1.29).

However, clear effects favouring the intervention programme were noted for head/neck injuries (Incidence RR=0.72, 0.51-1.01), upper limb injuries (Burden RR=0.66, 0.40-1.10), and concussion (Incidence RR=0.71, 0.48-1.05).

<<<<<<Figure 2 Here>>>>>>

9 **Per-protocol analyses**

Per-protocol trial arm comparisons (intervention, 4 schools, 7 teams; control, 3 schools, 5 teams) revealed that teams completing the intervention programme 3 times or more per week suffered 72% fewer overall match injuries (Incidence RR=0.28, 0.14-0.51), 72% fewer contact-related injuries (Incidence RR=0.28, 0.14-0.56), 50% fewer days lost to contact injuries (Burden RR=0.50, 0.21-1.18), 81% fewer upper limb injuries (Incidence RR=0.19, 0.07-0.50), 70% fewer lower limb injuries (Incidence RR=0.30, 0.10-0.92), and 59% fewer concussions (Incidence RR=0.41, 0.17-0.99) than teams that completed the control programme 3 or more times per week (Figure 3).

Per-protocol analyses conducted in the intervention arm indicated that teams typically completing at least 3 sessions per week with the intervention programme (4 schools, 7 teams) suffered 39% fewer match injuries (Incidence RR=0.61, 0.42-0.88), 48% fewer days
lost to match injuries (Burden RR=0.52, 0.29-0.93), 42% fewer match contact injuries (Incidence RR=0.58, 0.41-0.82), and 55% fewer days lost to match contact injuries (Burden RR=0.45, 0.25-0.82) than teams that completed the intervention programme fewer than 3-times per week (10 schools, 25 teams). Effects of intervention programme dose were unclear for upper limb injuries, lower limb injuries, and concussion.

**DISCUSSION**

This study aimed to determine the efficacy of a movement control exercise programme for preventing injury in youth rugby players, and to assess the effect of programme dose on injury measures. Following intention-to-treat analyses, effects of the trial arm were unclear for overall match injury. Per-protocol trial arm comparisons under conditions of high dose (≥3 weekly programme sessions) revealed clear reductions for the intervention arm for overall match injury, contact-related injury, upper and lower extremity injury and concussion incidence values. Moreover, a higher intervention programme dose was shown to reduce the incidence and burden of overall match injuries and contact injuries compared with lower intervention programme doses (<3 weekly programme completions).

**Intention-to-treat analyses**

Intention-to-treat analyses indicated unclear effects of trial arm for overall match injury (Incidence RR=0.85, Burden RR=0.83) and match contact injury (Incidence RR=0.85; Burden RR=0.88). The 15% reduction in overall match injury incidence in this study is lower than the 41-56% reductions noted in other studies conducted in male basketball and soccer players,[8,10,11] which may be partly attributed to differences between definitions of reportable injuries, programme content, or the distribution of injury types and locations between the respective sports, i.e. proportion of non-contact lower limb injuries. However, clear effects favouring the intervention exercise programme were noted for head/neck injury.
incidence (Incidence RR=0.72) and concussion incidence (Incidence RR=0.71). Sixty-two percent of reported head/neck injuries in the trial were attributed to concussion, and therefore the reductions in head/neck injury incidence were likely because of reductions in concussion incidence. Concussion is a priority for prevention across contact and collision sports due to potential concern over medium- and long-term player welfare.[29,30] Thus, the substantially reduced concussion incidence across the intervention arm is a very promising finding with regards to current efforts to reduce the risk of concussion.

Neck strength has been shown to be substantially lower in adolescent rugby players when compared with adults players despite similar peripheral strength profiles.[31] Increased concussion risk is associated with lower neck strength, highlighting this characteristic as a potentially modifiable risk factor.[12] Enhancing neck muscle strength may prevent concussion by improving the dissipation of impact forces transmitted to the brain.[32,33] Therefore, it is possible that the neck resistance exercises in the intervention exercise programme contributed to reduced concussion incidence via this mechanism. Neck pain is a common physical complaint among young sportspeople participating in collision sports,[34,35] and may be associated with increased concussion risk.[33] Given that acute and cumulative rugby exposure can adversely impact neck function,[36-38] the neck resistance exercises may also have contributed to preserving neck function during the playing season,[39] in turn reducing concussion incidence.

Upper limb injuries are common in contact sports and can also result in substantial time-loss in youth rugby players.[5,40] Teams in the intervention trial arm suffered substantially fewer days absence due to upper limb injuries than teams in the control arm (Burden RR=0.66). Little is known about the underlying risk factors and mechanisms for upper limb injuries, and examples of evidence-based upper limb injury prevention are scarce.[41] Reduced glenohumeral rotation and rotator cuff muscle strength imbalances may be modifiable risk factors for shoulder injuries in rugby players.[42] The intervention programme may have improved joint kinematics and force-handling capabilities within the upper limb as a result of
incorporating resistance and plyometric training of upper body regions,[43,44] thus implying that reducing upper limb injury risk across youth contact sports is possible through improving upper limb strength, stability, and mobility.

**Per-protocol analyses**

The lack of clear substantial effects for overall match and contact-related injuries following intention-to-treat analyses should be considered in the context of dose, which may have affected these outcomes. Although mean intervention programme dose in this study was higher (1.9 completions per week) than has been reported in previous studies (1.3-1.4 completions per week),[45,46] the level of dose that teams received in the intervention trial arm may have been insufficient to demonstrate a clear effect on overall match injuries. Greater effects of preventive exercise programmes may be realised if regularly used at least 3 times per week.[25] Trial arm comparisons conducted on a per-protocol basis showed that intervention trial arm teams that regularly completed the programme more than 3 times per week suffered 72% fewer overall match injuries, 72% fewer contact-related injuries, 81% fewer upper limb injuries, 70% fewer lower limb injuries, and 59% fewer concussions than control teams with an equivalent dose. When per-protocol analyses were conducted within the intervention arm, teams that regularly completed the programme over 3 times per week suffered 39% fewer match injuries, 48% fewer days lost to match injuries 42% fewer contact injuries and 55% fewer days lost to contact injuries than teams with less than 3 weekly programme completions. Regularly performing a preventive exercise programme 3 times per week over a sustained period has been shown to improve markers for neuromuscular control and muscle strength in male soccer players.[47] Therefore, these physiological benefits may explain the enhanced effects noted in this study with a high dose of the intervention programme use compared with the control programme and a lower dose of the intervention programme.

Evidence of a dose-response effect on overall and contact-related injuries in this study presents wider applications of the dose-response effect of preventive exercise programmes,
and has the potential to inform subsequent implementation attempts through identifying a minimum effective dose in this population. The collective findings from the intention-to-treat and per-protocol analyses highlight that teams involved in contact sports can obtain benefit from using preventive exercise programmes, but more importantly, regular exposure of more than 3 times per week can result in substantial injury risk reduction.

Limitations and future directions

There were several limitations to this study that should be acknowledged. Firstly, the research team members that ran the pre-trial workshops and conducted pre-season visits were not blinded to the programme allocation for each school, creating potential bias between the two groups in terms of the processes followed and information disseminated at these workshops; this was mitigated through use of a unified workshop format. Secondly, individual player compliance was not monitored during the study. Results of previous studies have indicated that individual player compliance may be a more sensitive measure than team compliance in determining the influence of compliance on programme efficacy,[45,46] but puts considerable strain on coaches, and so wasn’t feasible in this setting. Thirdly, it wasn’t possible to validate coach compliance reports or to monitor exercise fidelity the quality of performing the exercises through unannounced visits or observations, given that schools have strict policies around access to premises. Any limits of fidelity with which teams used the programmes is uncertain, but may actually have mediated programme efficacy along with dose and compliance.[48]

Further work is required to understand the mechanistic bases by which the intervention exercise programme reduced injury outcomes, particularly in relation to the proposed effects of the programme on neck strength and function in reducing concussion incidence, as well as kinematics and force handling capacities in the upper limb. Determining efficacy is a crucial step towards effecting a public health impact of injury prevention measures in rugby, although results of this controlled trial alone are not sufficient to translate to reducing injuries in “real world” contexts.[49,50] Further research is required to further understand the
contexts into which the exercise programme would be implemented, as well as identifying what factors may facilitate or inhibit programme use.[18] In particular, studies should be directed to identifying what factors could facilitate or inhibit teams from completing the intervention programme 3 times per week.

CONCLUSION

Although intention-to-treat results highlighted trivial effects of the intervention exercise programme on overall match injury incidence when compared with the control exercise programme, a substantial reduction in overall match injury incidence was evident from per-protocol trial arm comparisons under conditions of high programme dose (3 or more weekly sessions). Notable beneficial effects of the preventive programme on upper and lower extremity injuries and concussion incidence also have important implications for the reduction of these priority injury types in youth rugby.
ACKNOWLEDGEMENTS
The authors would like to acknowledge with sincere gratitude all school coaches and medical staff for the recording of injury, exposure, and compliance data during the study period. Furthermore, thanks are expressed to members of the project’s ‘Technical Project Group’: who contributed to the development of both exercise programmes: Matthew Cross, Alasdair Dempsey, Carolyn Emery, Richard Mack, Katie Morris, Simon Roberts, Des Ryan, Evert Verhagen, Sean Williams, Shaun Williams

COMPETING INTERESTS
None

FUNDING
This research is funded by the Rugby Football Union.

CONTRIBUTORSHIP STATEMENT
GT, KS, ME & SK initiated the overall project. MH, KS, SW, CM, ME, SK & GT conceived and designed the study. MH analysed the data and prepared the first draft of the manuscript. All authors made substantial contributions to revision of the manuscript prior to submission.

evidence being translated into the football field? *Journal of Science and Medicine in
What are the new findings?

- Intention-to-treat analyses revealed that the intervention programme substantially reduced upper limb injury burden (RR=0.66, 90% CL: 0.40-1.10) and concussion incidence (RR=0.71, 90% CL: 0.48-1.05) compared with the control programme.

- Completing the intervention programme 3 times per week led to substantial reductions of 72% in overall match injury incidence (RR=0.28, 90% CL: 0.14-0.51) and 72% in contact-related injury incidence (RR=0.28, 90% CL: 0.28-0.56) compared with the control programme.

How might these impact on clinical practice in the near future?

- These findings provide encouraging evidence that a pre-activity preventive exercise programme can substantially reduce injury risk in youth rugby.

- Notable reductions in upper extremity injuries and concussion offer promising implications for the prevention of these high-risk injury types in young rugby players.

- Findings also outline a minimum effective dose of 3 sessions a week whereby programme efficacy can be optimised.
Figure and Table Legends

**Figure 1** Flow diagram presenting the recruitment and retention of participants through the study.

**Table 1** Summary and comparisons of player characteristics between the intervention (n=1,325 players) and control (n=1,127 players) groups.

**Table 2** Descriptive statistics for match injuries across the control and intervention cohorts.

**Figure 2** Forest plot detailing the results of the intention-to treat-analyses for effects of trial arm on injury measures (n=31 schools, 83 teams). Data points represent RR of injury measures in the intervention arm relative to the control arm (reference group, RR=1.00). Dotted vertical lines represent thresholds for smallest worthwhile effects (RR=0.90 and 1.11). Data labels represent % likelihood that each effect favours the intervention | is trivial | favours the control, for outcome variables that demonstrate a clear effect of trial arm allocation. *Likely, **Very Likely, ***Most Likely.

**Figure 3** Forest plot illustrating the results of the per-protocol analyses on the effect of trial arm on injury measures in teams with a mean programme completion rate of more than 3 completions per week (n=7 schools, 12 teams). Data points represent RR of injury measures in the intervention arm relative to the control arm (reference group, RR=1.00). Dotted vertical lines represent thresholds for smallest worthwhile effects (RR= 0.90 and 1.11). Data labels represent % likelihood that each effect favours the intervention | is trivial | favours the control, for outcome variables which demonstrate a clear effect of trial arm allocation. *Likely, **Very Likely, ***Most Likely.
Figure 4  Forest plot illustrating the effects of intervention programme dose on injury measures (n= 14 schools, 32 teams). Data points represent RR of injury measures in teams completing ≥3 sessions per week relative to teams completing <3 sessions per week (RR=1.00). Dotted vertical lines represent thresholds for smallest worthwhile effect (RR= 0.90 and 1.11). Data labels represent % likelihood that each effect favours ≥3 completions per week | is trivial | favours <3 completions per week, for outcome variables which demonstrate a clear effect of programme dose.*Likely, **Very Likely, ***Most Likely.
