Logic programming: laxness and saturation☆

Abstract

A propositional logic program \( P \) may be identified with a \( P_f P_f \)-coalgebra on the set of atomic propositions in the program. The corresponding \( C(\mathcal{P}_f \mathcal{P}_f) \)-coalgebra, where \( C(\mathcal{P}_f \mathcal{P}_f) \) is the cofree comonad on \( \mathcal{P}_f \mathcal{P}_f \), describes derivations by resolution. That correspondence has been developed to model first-order programs in two ways, with lax semantics and saturated semantics, based on locally ordered categories and right Kan extensions respectively. We unify the two approaches, exhibiting them as complementary rather than competing, reflecting the theorem-proving and proof-search aspects of logic programming. While maintaining that unity, we further refine lax semantics to give finitary models of logic programs with existential variables, and to develop a precise semantic relationship between variables in logic programming and worlds in local state.

Keywords: Logic programming, coalgebra, coinductive derivation tree, Lawvere theories, lax transformations, saturation

1. Introduction

Over recent years, there has been a surge of interest in category theoretic semantics of logic programming. Research has focused on two ideas: lax semantics, proposed by the current authors and collaborators [1], and saturated semantics, proposed by Bonchi and Zanasi [2]. Both ideas are based on coalgebra, agreeing on variable-free logic programs. Both ideas use subtle, well-established category theory, associated with locally ordered categories and with right Kan extensions respectively [3]. And both elegantly clarify and extend established logic programming constructs and traditions, for instance [4] and [5].

Until now, the two ideas have been presented as alternatives, competing with each other rather than complementing each other. A central thesis of this paper is that the competition is illusory, the two ideas being two views of a single, elegant body of theory, those views reflecting different but complementary aspects of logic programming, those aspects broadly corresponding with the notions of theorem proving and proof search. Such reconciliation has substantial consequences. In particular, it means that whenever one further refines one approach, as we shall do to the original lax approach in two substantial ways here, one should test whether the proposed refinement also applies to the other approach, and see what consequences it has from the latter perspective.

The category theoretic basis for both lax and saturated semantics is as follows. It has long been observed, e.g., in [6, 7], that logic programs induce coalgebras, allowing coalgebraic modelling of their operational semantics. Using the definition of logic program in Lloyd’s book [8], given a set of atoms \( \text{At} \), one can identify a variable-free logic program \( P \) built over \( \text{At} \) with a \( P_fP_f \)-coalgebra structure on \( \text{At} \), where \( P_f \) is the finite powerset functor on \( \text{Set} \): each atom is the head of finitely many clauses in \( P \), and the body of each clause contains finitely many atoms. It was shown in [9] that if \( C(P_fP_f) \) is the cofree comonad on \( P_f \), then, given a logic program \( P \) qua \( P_fP_f \)-coalgebra, the corresponding \( C(P_fP_f) \)-coalgebra structure characterises the and-or derivation trees generated by \( P \), cf. [4]. That fact has formed the basis for our work on lax semantics [1, 10, 11, 12, 13] and for Bonchi and Zanasi’s work on saturation semantics [14, 2].

In attempting to extend the analysis to arbitrary logic programs, both groups followed the tradition of [15, 6, 5, 16]: given a signature \( \Sigma \) of function symbols, let \( L_{\Sigma} \) denote the Lawvere theory generated by \( \Sigma \), and, given a logic program \( P \) with function symbols in \( \Sigma \), consider the functor category \( [L_{\Sigma}^{op},\text{Set}] \), extending the set \( \text{At} \) of atoms in a variable-free logic program to the functor from \( L_{\Sigma}^{op} \) to \( \text{Set} \) sending a natural number \( n \) to the set \( \text{At}(n) \) of atomic formulae with at most \( n \) variables generated by the function symbols in \( \Sigma \) and the predicate symbols in \( P \). We all sought to model \( P \) by a \( [L_{\Sigma}^{op},P_fP_f] \)-coalgebra \( p : \text{At} \rightarrow P_fP_f\text{At} \) that, at \( n \), takes an atomic formula \( A(x_1,\ldots,x_n) \) with at most \( n \) variables, considers all substitutions of clauses in \( P \) into clauses with variables among \( x_1,\ldots,x_n \) whose head agrees with \( A(x_1,\ldots,x_n) \), and gives the set of sets of atomic formulae in antecedents, naturally extending the construction for variable-free logic programs. However, that idea is too simple for two reasons. We all dealt with the second problem in the same way, so we shall discuss it later, but the first problem is illustrated by the following example.

**Example 1.** ListNat (for lists of natural numbers) denotes the logic program.
1. \( \text{nat}(0) \leftarrow \)
2. \( \text{nat}(s(x)) \leftarrow \text{nat}(x) \)
3. \( \text{list}(!) \leftarrow \)
4. \( \text{list}(\text{cons}(x,y)) \leftarrow \text{nat}(x), \text{list}(y) \)

ListNat has nullary function symbols \( 0 \) and \( \text{nil} \), a unary function symbol \( s \),
and a binary function symbol \texttt{cons}. So the signature $\Sigma$ of \texttt{ListNat} contains four elements.

There is a map in $\mathcal{L}_\Sigma$ of the form $0 \to 1$ that models the nullary function symbol $0$. So, naturality of the map $p : \text{At} \to P_f P_f \text{At}$ in $[\mathcal{L}_\Sigma^{op}, \mathbf{Set}]$ would yield commutativity of the diagram

\[
\begin{array}{c}
\text{At}(1) \\
\downarrow \quad \downarrow \\
\text{At}(0)
\end{array}
\xymatrix{ & P_f P_f \text{At}(1) \ar[ll]_{p_1} \\
\text{At}(0) \ar[u] \\
\text{At}(0) \ar[u] \ar[r]_{p_0} & P_f P_f \text{At}(0)}
\]

But consider $\text{nat}(x) \in \text{At}(1)$: there is no clause of the form $\text{nat}(x) \leftarrow$ in \texttt{ListNat}, so commutativity of the diagram would imply that there cannot be a clause in \texttt{ListNat} of the form $\text{nat}(0) \leftarrow$ either, but in fact there is one. Thus $p$ is not a map in the functor category $[\mathcal{L}_\Sigma^{op}, \mathbf{Set}]$.

\textbf{Problem 1.} As illustrated by Example 1, i.e., in \texttt{ListNat}, the natural construction of $p : \text{At} \to P_f P_f \text{At}$ does not form a map, i.e., yield a natural transformation, in $[\mathcal{L}_\Sigma^{op}, \mathbf{Set}]$.

Proposed resolutions to Problem 1 diverged: at CALCO in 2011, we proposed lax transformations [17], then at CALCO 2013, Bonchi and Zanasi proposed saturation semantics [14]. First we shall describe our approach.

Our approach was to relax the naturality condition on $p$ to a subset condition, following [18, 19, 20], so that, given a map in $\mathcal{L}_\Sigma$ of the form $f : n \to m$, the diagram

\[
\begin{array}{c}
\text{At}(m) \\
\downarrow \quad \downarrow \\
\text{At}(n)
\end{array}
\xymatrix{ & P_f P_f \text{At}(m) \ar[ll]_{p_m} \\
\text{At}(f) \ar[u] \\
\text{At}(n) \ar[u] \ar[r]_{p_n} & P_f P_f \text{At}(n)}
\]

need not commute, but rather the composite via $P_f P_f \text{At}(m)$ need only yield a subset of that via $\text{At}(n)$. So, for example, $p_1(\text{nat}(x))$ could be the empty set while $p_0(\text{nat}(0))$ could be non-empty in the semantics for \texttt{ListNat} as required. We extended \texttt{Set} to \texttt{Poset} in order to express such laxness, and we adopted established category theoretic research on laxness, notably that of [20], in order to prove that a cofree comonad exists and, on programs such as \texttt{ListNat}, behaves as we wish. This agrees with, and is indeed an instance of, He Jifeng and Tony Hoare’s use of laxness to model data refinement [21, 22, 23, 24].
Bonchi and Zanasi’s approach was to use saturation semantics [14, 2], following [6]. The key category theoretic result that supports it asserts that, regarding \( \text{ob}(\mathcal{L}_\Sigma) \), equally \( \text{ob}(\mathcal{L}_\Sigma)^\text{op} \), as a discrete category with inclusion functor \( I : \text{ob}(\mathcal{L}_\Sigma) \rightarrow \mathcal{L}_\Sigma \), the functor

\[
[I, \text{Set}] : [\mathcal{L}_\Sigma^\text{op}, \text{Set}] \rightarrow [\text{ob}(\mathcal{L}_\Sigma)^\text{op}, \text{Set}]
\]

that sends \( H : \mathcal{L}_\Sigma^\text{op} \rightarrow \text{Set} \) to the composite \( HI : \text{ob}(\mathcal{L}_\Sigma)^\text{op} \rightarrow \text{Set} \) has a right adjoint, given by right Kan extension. The data for \( p : \text{At} \rightarrow \text{PfPfAt} \), although not forming a map in \( [\mathcal{L}_\Sigma^\text{op}, \text{Set}] \), may be seen as a map in \( [\text{ob}(\mathcal{L}_\Sigma)^\text{op}, \text{Set}] \). So, by the adjointness, the data for \( p \) corresponds to a map \( \bar{p} : \text{At} \rightarrow R(\text{PfPfAtI}) \) in \( [\mathcal{L}_\Sigma^\text{op}, \text{Set}] \), thus to a coalgebra on \( \text{At} \) in \( [\mathcal{L}_\Sigma^\text{op}, \text{Set}] \), where \( R(\text{PfPfAtI}) \) is the right Kan extension of \( \text{PfPfAtI} \) along the inclusion \( I \). The right Kan extension is defined by

\[
R(\text{PfPfAtI})(n) = \prod_{m \in \mathcal{L}_\Sigma} (\text{PfPfAt}(m))^{\mathcal{L}_\Sigma(m,n)}
\]

and the function

\[
\bar{p}(n) : \text{At}(n) \rightarrow \prod_{m \in \mathcal{L}_\Sigma} (\text{PfPfAt}(m))^{\mathcal{L}_\Sigma(m,n)}
\]

takes an atomic formula \( A(x_1, \ldots, x_n) \), and, for every substitution for \( x_1, \ldots, x_n \) generated by the signature \( \Sigma \), gives the set of sets of atomic formulae in the tails of clauses with head \( A(t_1, \ldots, t_n) \), where the \( t_i \)'s are determined by the substitution. By construction, \( \bar{p} \) is natural, but one quantifies over all possible substitutions for \( x_1, \ldots, x_n \) in order to obtain that naturality, and one ignores the laxness of \( p \).

As we shall show in Section 5, the two approaches can be unified. If one replaces

\[
[I, \text{Set}] : [\mathcal{L}_\Sigma^\text{op}, \text{Set}] \rightarrow [\text{ob}(\mathcal{L}_\Sigma)^\text{op}, \text{Set}]
\]

by the inclusion

\[
[\mathcal{L}_\Sigma^\text{op}, \text{Poset}] \rightarrow \text{Lax}(\mathcal{L}_\Sigma^\text{op}, \text{Poset})
\]

\( [\mathcal{L}_\Sigma^\text{op}, \text{Poset}] \) being a full subcategory of \( [\mathcal{L}_\Sigma^\text{op}, \text{Poset}] \), one obtains exactly Bonchi and Zanasi’s correspondence between \( p \) and \( \bar{p} \), with exactly the same formula, starting from lax transformations as we proposed. Thus, from a category theoretic perspective, saturation can be seen as complementary to laxness rather than as an alternative to it. This provides a robustness test for future refinements to models of logic programming: a refinement of one view of category theoretic semantics can be tested by its effect on the other. We now turn to such refinements.

Recently, we have refined lax semantics in two substantial ways, the first of which was the focus of the workshop paper [25] that this paper extends, with the second being to start to build a precise relationship with the semantics for local variables [26], which is new here. For the first, a central contribution of
lax semantics has been the inspiration it provided towards the development of an efficient logic programming algorithm [1, 10, 11, 12, 13]. That development drew our attention to the semantic significance of existential variables: such variables do not appear in ListNat, and they are not needed for a considerable body of logic programming, but they do appear in logic programs such as the following, which is a leading example in Sterling and Shapiro’s book [27].

Example 2. GC (for graph connectivity) denotes the logic program
1. connected(x, x) ←
2. connected(x, y) ← edge(x, z), connected(z, y)

There is a variable z in the tail of the second clause of GC that does not appear in its head, whereas no such variable appears in ListNat. Such a variable is called an existential variable, the presence of which challenges the algorithmic significance of lax semantics. In describing the putative coalgebra \( p : \text{At} \rightarrow P_f P_f \text{At} \) just before Example 1, we referred to all substitutions of clauses in \( P \) into clauses with variables among \( x_1, \ldots, x_n \) whose head agrees with \( A(x_1, \ldots, x_n) \). If there are no existential variables, that amounts to term-matching, which is algorithmically efficient; but if existential variables do appear, the mere presence of a unary function symbol generates an infinity of such substitutions, creating algorithmic difficulty, which, when first introducing lax semantics, we avoided modelling by replacing the outer instance of \( P_f \) by \( P_c \), thus allowing for countably many choices.

Bonchi and Zanasi, in [14, 2], followed the lead of lax semantics in using \( P_c \) rather than \( P_f \) in order to account for existential variables, but one needs a careful study to see that. In saturated semantics, countability arises in two ways: applying the right Kan extension \( R \) yields countability as there may be countably many substitutions for variables; and using \( P_c \) rather than \( P_f \) also yields countability. In the absence of existential variables, Bonchi and Zanasi could have applied saturation to the map \( p : \text{At} \rightarrow P_f P_f \text{At} \), with the right Kan extension generating the countability required for saturation. However, in the presence of existential variables, there is no such map into \( P_f P_f \text{At} \) to which to apply saturation. So for saturated semantics, our analysis of existential variables makes for a subtle difference, clarifying where countability is required.

That is the second of the two problems mentioned just before Example 1. More succinctly, it may be expressed as follows:

Problem 2. As illustrated by Example 2, an arbitrary logic program does not generate a map of the form \( p : \text{At} \rightarrow P_f P_f \text{At} \). Previous work addressed that by an artificial use of countability.

We have long sought a solution to Problem 2. We finally found and presented such a resolution in the workshop paper [25] that this paper extends. We both refine it a little more, as explained later, and give more detail here.

The conceptual key to the resolution was to isolate and give finitary lax semantics to the notion of coinductive tree [28, 1]. Coinductive trees arise from
term-matching resolution \[28, 1\], which is a variant of SLD-resolution. Term-
matching captures the theorem proving aspect of logic programming, which
is distinct from, but complementary with, its problem solving aspect, which
is captured by SLD-resolution \[12, 11\]. The difference is that in the term-
matching approach, one only substitutes in a goal after having exhausted all
possible term-matching, whereas in SLD-resolution, one uses full unification at
any time. We called the derivation trees arising from term-matching coinductive
trees in order to mark their connection with coalgebraic logic programming,
which we also developed.

Syntactically, one can observe the difference between lax semantics and sa-
turation semantics in that lax semantics models coinductive trees, which are
finitely branching, whereas saturation involves infinitely many possible substi-
tutions, leading Bonchi and Zanasi to model different kinds of trees, their focus
being on proof search rather than on theorem proving.

Chronologically, we introduced lax semantics in 2011 as above \[17\]; lax se-
manitics inspired us to investigate term-matching and to introduce the notion
of coinductive tree \[28\]; because of the possibility of existential variables, our
lax semantics for coinductive trees, despite inspiring the notion, was potentially
infinite \[1\]; so we have now refined lax semantics to ensure finiteness of the
semantics for coinductive trees, even in the presence of existential variables \[25\],
introducing it in the workshop paper that this paper extends. We further refine
lax semantics here to start to build a precise relationship with the semantics of
local variables \[26\], which we plan to develop further in future. We regard it
as positive that lax semantics brings to the fore, in semantic terms, the signifi-
cance of existential variables, and allows a precise semantic relationship between
the role of variables in logic programming and local variables as they arise in
programming more generally.

The semantics we give in this paper is subtly different to that in \[25\]. Here,
we disambiguate the role of \(P_f\) in our modelling of existential variables: in
Section 6, we consider \(\int At\), then apply \(P_f P_f\) to it, whereas we mixed a con-
struction for \(\int\) with \(P_f\) in \[25\], but that does not quite match the modelling
of local state. We also give far more detail throughout this paper: in giving
examples, in explaining the relationship with Bonchi and Zanasi’s saturated
semantics, in proofs, and in developing the relationship with local state.

The paper is organised as follows. In Section 2, we set logic programming ter-
minology, explain the relationship between term-rewriting and SLD-resolution,
and introduce the notion of coinductive tree. In Section 3, we give semantics
for variable-free logic programs. This semantics could equally be seen as lax
semantics or saturated semantics, as they agree in the absence of variables. In
Section 4, we model coinductive trees for logic programs without existential
variables and explain the difficulty in modelling coinductive trees for arbitrary
logic programs. In Section 5, we recall saturation semantics and make precise
the relationship between it and lax semantics. We devote Section 6 of the paper
to refining lax semantics, while maintaining the relationship with saturation
semantics, to model the coinductive trees generated by logic programs with ex-
istential variables, and in Section 7, we start to build a precise relationship with
2. Theorem proving in logic programming

A signature $\Sigma$ consists of a set $F$ of function symbols $f, g, \ldots$ each equipped with an arity. Nullary (0-ary) function symbols are constants. For any set $Var$ of variables, the set $Ter(\Sigma)$ of terms over $\Sigma$ is defined inductively as usual:

- $x \in Ter(\Sigma)$ for every $x \in Var$.
- If $f$ is an $n$-ary function symbol ($n \geq 0$) and $t_1, \ldots, t_n \in Ter(\Sigma)$, then $f(t_1, \ldots, t_n) \in Ter(\Sigma)$.

A substitution over $\Sigma$ is a (total) function $\sigma : Var \rightarrow Ter(\Sigma)$. Substitutions are extended from variables to terms as usual: if $t \in Ter(\Sigma)$ and $\sigma$ is a substitution, then the application $\sigma(t)$ is a result of applying $\sigma$ to all variables in $t$. A substitution $\sigma$ is a unifier for $t, u$ if $\sigma(t) = \sigma(u)$, and is a matcher for $t$ against $u$ if $\sigma(t) = u$. A substitution $\sigma$ is a most general unifier (mgu) for $t$ and $u$ if it is a unifier for $t$ and $u$ and is more general than any other such unifier, i.e., all unifiers factor through any most general unifier. A most general matcher (mgm) $\sigma$ for $t$ against $u$ is defined analogously.

In line with logic programming (LP) tradition [8], we consider a set $P$ of predicate symbols each equipped with an arity. It is possible to define logic programs over terms only, in line with the term-rewriting (TRS) tradition [29], as in [11], but we will follow the usual LP tradition here. That gives us the following inductive definitions of the sets of atomic formulae, Horn clauses and logic programs (we also include the definition of terms for convenience).

**Definition 1.**

Terms $Ter ::= Var \mid F(Ter, ..., Ter)$
Atomic formulae (or atoms) $At ::= P(Ter, ..., Ter)$
(Horn) clauses $HC ::= At ← At, ..., At$
Logic programs $Prog ::= HC, ..., HC$

In what follows, we will use letters $A, B, C, D$, possibly with subscripts, to refer to elements of $At$.

Given a logic program $P$, we may ask whether a given atom is logically entailed by $P$. E.g., given the program ListNat we may ask whether $\text{list}(\text{cons}(0, \text{nil}))$ is entailed by ListNat. The following rule, which is a restricted form of SLD-resolution, provides a semi-decision procedure to derive the entailment.

**Definition 2 (Term-matching (TM) Resolution).** Given a program $P$ and an atomic formula $A$, we say $P$ entails $A$, written as $P \vdash A$, if there is a derivation of $P \vdash A$ from an empty goal using the following rules:

$$
\frac{P \vdash [ ] \quad P \vdash \sigma A_1 \quad \cdots \quad P \vdash \sigma A_n} {P \vdash \sigma A} \text{ if } (A \leftarrow A_1, \ldots, A_n) \in P
$$
In contrast, the SLD-resolution rule could be presented in the following form:

\[ B_1, \ldots, B_j, \ldots, B_n \leadsto^p \sigma B_1, \ldots, \sigma A_1, \ldots, \sigma A_n, \ldots, \sigma B_n \]

if \((A \leftarrow A_1, \ldots, A_n) \in P\), and \(\sigma\) is the mgu of \(A\) and \(B_j\). The derivation for \(A\) succeeds when \(A \leadsto^p \[]\); we use \(\leadsto^*_p\) to denote several steps of SLD-resolution.

At first sight, the difference between TM-resolution and SLD-resolution may seem only to be notational. Indeed, both \(\text{ListNat} \vdash \text{list}(\text{cons}(0, \text{nil}))\) and \(\text{list}(\text{cons}(0, \text{nil})) \sim^{*}_{\text{ListNat}} \[]\) by the above rules (see also Figure 1). However, \(\text{ListNat} \not\vdash \text{list}(\text{cons}(x, y))\) whereas \(\text{list}(\text{cons}(x, y)) \sim^{*}_{\text{ListNat}} \[]\). And, even more mysteriously, \(\text{GC} \not\vdash \text{connected}(x, y)\) whereas \(\text{connected}(x, y) \sim^{*}_{\text{GC}} \[]\).

In fact, TM-resolution reflects the theorem proving aspect of LP: the rules of Definition 2 can be used to semi-decide whether a given term \(t\) is entailed by \(P\). In contrast, SLD-resolution reflects the problem solving aspect of LP: using the SLD-resolution rule, one asks whether, for a given \(t\), a substitution \(\sigma\) can be found such that \(P \vdash \sigma(t)\). There is a subtle but important difference between these two aspects of proof search.

For example, when considering the successful derivation \(\text{list}(\text{cons}(x, y)) \sim^{*}_{\text{ListNat}} \[]\), we assume that \(\text{list}(\text{cons}(x, y))\) holds only relative to a computed substitution, e.g. \(x \mapsto 0, y \mapsto \text{nil}\). Of course this distinction is natural from the point of view of theorem proving: \(\text{list}(\text{cons}(x, y))\) is not a “theorem” in this generality, but its special case, \(\text{list}(\text{cons}(0, \text{nil}))\), is. Thus, \(\text{ListNat} \vdash \text{list}(\text{cons}(0, \text{nil}))\) but \(\text{ListNat} \not\vdash \text{list}(\text{cons}(x, y))\) (see also Figure 1). Similarly, \(\text{connected}(x, y) \sim^{*}_{\text{GC}} \[]\) should be read as: \(\text{connected}(x, y)\) holds relative to the computed substitution \(y \mapsto x\).

According to the soundness and completeness theorems for SLD-resolution [8], the derivation \(\sim\) has existential meaning, i.e. when \(\text{list}(\text{cons}(x, y)) \sim^{*}_{\text{ListNat}} \[]\), the successful goal \(\text{list}(\text{cons}(x, y))\) is not meant to be read as universally quantified over \(x\) and \(y\). In contrast, TM-resolution proves a universal statement. So \(\text{GC} \vdash \text{connected}(x, x)\) reads as: \(\text{connected}(x, x)\) is entailed by \(\text{GC}\) for any \(x\).

Much of our recent work has been devoted to formal understanding of the relation between the theorem proving and problem solving aspects of LP [11, 12]. The type-theoretic semantics of TM-resolution, given by “Horn clauses as types, \(\lambda\)-terms as proofs” is given in [12, 13].

Definition 2 gives rise to derivation trees. E.g. the derivation (or, equivalently, the proof) for \(\text{ListNat} \vdash \text{list}(\text{cons}(0, \text{nil}))\) can be represented by the following derivation tree:

```
list(cons(0, nil))
   /   \
nat(0) list(nil)
  |     |
[]  []  []
```
In general, given a term \( t \) and a program \( P \), more than one derivation for \( P \vdash t \) is possible. For example, if we add a fifth clause to the program \( ListNat \):

5. \( list(\text{cons}(0,x)) \leftarrow list(x) \)

then yet another, alternative, proof is possible for the extended program:

\[ ListNat^+ \vdash list(\text{cons}(0,\text{nil})) \]

via Clause 5:

\[
\begin{align*}
\text{list(cons(0,nil))} \\
\text{[ ]}
\end{align*}
\]

\[
\begin{align*}
\text{list(nil)} \\
\text{[ ]}
\end{align*}
\]

To reflect the choice of derivation strategies at every stage of the derivation, we introduce a new kind of node called an \textit{or-node}, which we depict by a \( \bullet \)-node, e.g., as in Figure 1.

This intuition is made precise in the following definition of a \textit{coinductive tree}, which first appeared in [17, 1] and was refined in [11] under the name of a rewriting tree. Over a succession of papers, we have made minor modifications and a few minor corrections to the precise formulation of the notion of coinductive tree, but the idea and application has remained the same.

**Definition 3 (Coinductive tree).** Let \( P \) be a logic program and \( A \) be an atomic formula. The coinductive tree for \( A \) is the possibly infinite tree \( T \) satisfying the following properties.

- the root of \( T \) is labelled by \( A \)
- Each node in \( T \) is either an \textit{and-node} or an \textit{or-node}
- Each or-node is labelled by \( \bullet \)
• Each and-node is labelled by an atom.

• For every and-node $A'$ occurring in $T$, if there is a clause $C_i$ in $P$ of the form $B_i \leftarrow B_i^1, \ldots, B_i^{n_i}$, such that there is an mgm $\theta$ of $B_i$ against $A'$, then $A'$ has an or-node as a child, and that or-node has children given by and-nodes $\theta(B_i^j), \ldots, \theta(B_i^{k})$, where $\{B_j, \ldots, B_k\} \subseteq \{B_1, \ldots, B_{n_i}\}$ and $B_j, \ldots, B_k$ is the maximal such set for which $\theta(B_i^j), \ldots, \theta(B_i^{k})$ are distinct.

Note the use of mgms (rather than mgus) in the last item. There may exist clauses with empty antecedents: some such exist in Figure 1. An or-node, thus a •-node with a single child labelled [ ], represents such a clause.

Coinductive trees provide a convenient model for proofs by TM-resolution. Note that coinductive trees are necessarily finitely branching, logic programs being inherently finite.

Let us make one final observation on TM-resolution. Generally, given a program $P$ and an atom $t$, one can prove that

$$t \xrightarrow{\ast} [ ]$$

with computed substitution $\sigma$ if and only if $P \vdash \sigma t$.

This simple fact may leave the impression that proofs (and correspondingly coinductive trees) for TM-resolution are in some sense fragments of reductions by SLD-resolution. Compare, for example, the right-hand tree of Figure 1 before substitution with the larger left-hand tree obtained after the substitution. In this case, we could emulate the problem solving aspect of SLD-resolution by using coinductive trees and allowing the application of substitutions within coinductive trees, as was proposed in [28, 11, 12]. That works perfectly for programs such as ListNat, but not for existential programs: although there is a one step SLD-derivation for $\text{connected}(x, y) \sim_{GC} [ ]$ (with $y \mapsto x$), there is no TM-resolution proof for $\text{connected}(x, y)$, as the derivation diverges and gives rise to the following infinite coinductive tree:

```
connected(x, y)
       \______________
     edge(x, z) connected(z, y)
         \______________
       edge(x, w) connected(w, y)
               \______________
                 \______________
```

The above tree is not a fragment of the derivation $\text{connected}(x, y) \sim_{GC} [ ]$, moreover, it requires more (infinitely many) variables. Thus, the operational semantics of TM-resolution and SLD-resolution can be very different for existential programs, in regard both to termination and to the number of variables involved.
This issue is largely orthogonal to that of non-termination. Consider the non-terminating (but not existential) program Bad:

\[
\text{bad}(x) \leftarrow \text{bad}(x)
\]

For Bad, the operational behaviours of TM-resolution and SLD-resolution are similar: in both cases, derivations do not terminate, and both require only finitely many variables. Moreover, such programs can be analysed using similar coinductive methods in TM- and SLD-resolution [13, 30].

The problems caused by existential variables are known in the literature on theorem proving and term-rewriting [29]. In TRS [29], existential variables are not allowed to appear in rewriting rules, and in type inference based on term rewriting or TM-resolution, the restriction to non-existential programs is common [31].

So theorem-proving, in contrast to problem-solving, is modelled by term-matching; term-matching gives rise to coinductive trees; and as explained in the introduction and, in more detail, later, coinductive trees give rise to laxness. So in this paper, we use laxness to model coinductive trees, and thereby theorem-proving in LP, and we relate our semantics with Bonchi and Zanasi’s saturated semantics, which we believe primarily models the problem-solving aspect of logic programming.

Categorical semantics for existential programs, which are known to be challenging for theorem proving, is a central contribution of Section 6 and of this paper.

3. Semantics for variable-free logic programs

In this section, we recall and develop the work of [9], in regard to variable-free logic programs, i.e., we take \(\text{Var} = \emptyset\) in Definition 1. Variable-free logic programs are operationally equivalent to propositional logic programs, as substitutions play no role in derivations. In this (propositional) setting, coinductive trees resemble the and-or derivation trees known in the LP literature [4], and this semantics appears as the ground case of both lax semantics [1] and saturated semantics [2].

**Proposition 1.** For any set \(\text{At}\), there is a bijection between the set of variable-free logic programs over the set of atoms \(\text{At}\) and the set of \(P_fP_f\)-coalgebra structures on \(\text{At}\), where \(P_f\) is the finite powerset functor on \(\text{Set}\).

**Theorem 1.** Let \(C(P_fP_f)\) denote the cofree comonad on \(P_fP_f\). Then, given a logic program \(P\) over \(\text{At}\), equivalently \(p : \text{At} \rightarrow P_fP_f(\text{At})\), the corresponding \(C(P_fP_f)\)-coalgebra \(\overline{p} : \text{At} \rightarrow C(P_fP_f)(\text{At})\) sends an atom \(A\) to the coinductive tree for \(A\).

**Proof.** Applying the work of [32] to this setting, the cofree comonad is in general determined as follows: \(C(P_fP_f)(\text{At})\) is the limit of the diagram

\[
\ldots \rightarrow \text{At} \times P_fP_f(\text{At} \times P_fP_f(\text{At})) \rightarrow \text{At} \times P_fP_f(\text{At}) \rightarrow \text{At}
\]
with maps determined by the projection \( \pi_0 : \text{At} \times P_f P_f(\text{At}) \rightarrow \text{At} \), with applications of the functor \( \text{At} \times P_f P_f(-) \) to it.

Putting \( \text{At}_0 = \text{At} \) and \( \text{At}_{n+1} = \text{At} \times P_f P_f \text{At}_n \), and defining the cone

\[
\begin{align*}
p_0 &= \text{id} : \text{At} \rightarrow \text{At} (= \text{At}_0) \\
p_{n+1} &= (\text{id}, P_f P_f(p_n) \circ p) : \text{At} \rightarrow \text{At} \times P_f P_f \text{At}_n (= \text{At}_{n+1})
\end{align*}
\]

the limiting property of the diagram determines the coalgebra \( \overline{\text{p}} : \text{At} \rightarrow C(P_f P_f)(\text{At}) \). The image \( \overline{\text{p}}(\text{A}) \) of an atom \( \text{A} \) is given by an element of the limit, equivalently a map from \( 1 \) into the limit, equivalently a cone of the diagram over \( 1 \).

To give the latter is equivalent to giving an element \( \text{A}_0 \) of \( \text{At} \), specifically \( \text{p}_0(\text{A}) = \text{A} \), together with an element \( \text{A}_1 \) of \( \text{At} \times P_f P_f(\text{At}) \), specifically \( \text{p}_1(\text{A}) = (\text{A}, \text{p}_0(\text{A})) = (\text{A}, \text{p}(\text{A})) \), together with an element \( \text{A}_2 \) of \( \text{At} \times P_f P_f(\text{At} \times P_f P_f(\text{At})) \), etcetera. The definition of the coinductive tree for \( \text{A} \) is inherently coinductive, matching the definition of the limit, and with the first step agreeing with the definition of \( \text{p} \). Thus it follows by coinduction that \( \overline{\text{p}}(\text{A}) \) can be identified with the coinductive tree for \( \text{A} \).

**Example 3.** Let \( \text{At} \) consist of atoms \( \text{A}, \text{B}, \text{C}, \text{D} \). Let \( \text{P} \) denote the logic program

\[
\begin{align*}
\text{A} &\leftarrow \text{B}, \text{C} \\
\text{A} &\leftarrow \text{B}, \text{D} \\
\text{D} &\leftarrow \text{A}, \text{C}
\end{align*}
\]

So \( \text{p}(\text{A}) = \{\{\text{B}, \text{C}\}, \{\text{B}, \text{D}\}\} \), \( \text{p}(\text{B}) = \text{p}(\text{C}) = \emptyset \), and \( \text{p}(\text{D}) = \{\{\text{A}, \text{C}\}\} \).

Then, as depicted in Figure 2, \( \text{p}_0(\text{A}) = \text{A} \), which is the root of the coinductive tree for \( \text{A} \).

Then \( \text{p}_1(\text{A}) = (\text{A}, \text{p}(\text{A})) = (\text{A}, \{\{\text{B}, \text{C}\}, \{\text{B}, \text{D}\}\}) \), which consists of the same information as in the first three levels of the coinductive tree for \( \text{A} \), i.e., the root \( \text{A} \), two or-nodes, and below each of the two or-nodes, nodes given by each atom in each antecedent of each clause with head \( \text{A} \) in the logic program \( \text{P} \): nodes marked \( \text{B} \) and \( \text{C} \) lie below the first or-node, and nodes marked \( \text{B} \) and \( \text{D} \) lie below the second or-node, exactly as \( \text{p}_1(\text{A}) \) describes.

Continuing, note that \( \text{p}_1(\text{D}) = (\text{D}, \text{p}(\text{D})) = (\text{D}, \{\{\text{A}, \text{C}\}\}) \). So

\[
\begin{align*}
p_2(\text{A}) &= (\text{A}, P_f P_f(p_1)(\text{p}(\text{A}))) \\
&= (\text{A}, P_f P_f(p_1)(\{\{\text{B}, \text{C}\}, \{\text{B}, \text{D}\}\})) \\
&= (\text{A}, \{\{\{\{\text{B}, \emptyset\}, \{\text{C}, \emptyset\}\}, \{\{\text{B}, \emptyset\}, \{\text{D}, \{\{\text{A}, \text{C}\}\}\}\}\})
\end{align*}
\]

which is the same information as that in the first five levels of the coinductive tree for \( \text{A} \): \( \text{p}_1(\text{A}) \) provides the first three levels of \( p_2(\text{A}) \) because \( p_2(\text{A}) \) must map to \( p_1(\text{A}) \) in the cone; in the coinductive tree, there are two and-nodes at level 5, labelled by \( \text{A} \) and \( \text{C} \). As there are no clauses with head \( \text{B} \) or \( \text{C} \), no or-nodes lie
below the first three of the and-nodes at level 3. However, there is one or-node lying below D, it branches into and-nodes labelled by A and C, which is exactly as $p_1(A)$ tells us.

![Figure 2: The coinductive tree for $A$ and the program $P$ from Example 3.](image)

4. Lax semantics for logic programs

We now lift the restriction on $Var = \emptyset$ in Definition 1 and consider first-order terms and atoms in full generality.

There are several equivalent ways in which to describe the Lawvere theory generated by a signature. So, for precision, in this paper, we define the Lawvere theory $\mathcal{L}_\Sigma$ generated by a signature $\Sigma$ as follows: $\text{ob}(\mathcal{L}_\Sigma)$ is the set of natural numbers. For each natural number $n$, let $x_1, \ldots, x_n$ be a specified list of distinct variables. Define $\mathcal{L}_\Sigma(n, m)$ to be the set of $m$-tuples $(t_1, \ldots, t_m)$ of terms generated by the function symbols in $\Sigma$ and variables $x_1, \ldots, x_n$. Define composition in $\mathcal{L}_\Sigma$ by substitution.

One can readily check that these constructions satisfy the axioms for a category, with $\mathcal{L}_\Sigma$ having strictly associative finite products given by the sum of natural numbers. The terminal object of $\mathcal{L}_\Sigma$ is the natural number 0. There is a canonical identity-on-objects functor from $\text{Nat}^{op}$ to $\mathcal{L}_\Sigma$, just as there is for any Lawvere theory, and it strictly preserves finite products.

**Example 4.** Consider ListNat. The constants $\textit{O}$ and $\textit{nil}$ are maps from 0 to 1 in $\mathcal{L}_\Sigma$, $\textit{s}$ is modelled by a map from 1 to 1, and $\textit{cons}$ is modelled by a map from 2 to 1. The term $\textit{s}(\textit{O})$ is the map from 0 to 1 given by the composite of the maps modelling $\textit{s}$ and $\textit{O}$.

Given an arbitrary logic program $P$ with signature $\Sigma$, we can extend the set $At$ of atoms for a variable-free logic program to the functor $At : \mathcal{L}_\Sigma^{op} \to \text{Set}$ that sends a natural number $n$ to the set of all atomic formulae, with variables among $x_1, \ldots, x_n$, generated by the function symbols in $\Sigma$ and by the predicate symbols in $P$. A map $f : n \to m$ in $\mathcal{L}_\Sigma$ is sent to the function $At(f) : At(m) \to At(n)$ that sends an atomic formula $A(x_1, \ldots, x_m)$ to
A(f_1(x_1, \ldots, x_n)/x_1, \ldots, f_m(x_1, \ldots, x_n)/x_m), \text{i.e.,} \ At(f) \text{ is defined by substitution.}

As explained in the Introduction and in [9], we cannot model a logic program by a natural transformation of the form \( p : At \rightarrow P_f P_f At \) as naturality breaks down, e.g., in ListNat. So, in [17, 1], we relaxed naturality to lax naturality. In order to define it, we extended \( At : \mathcal{L}_\Sigma^{op} \rightarrow \text{Set} \) to have codomain Poset by composing \( At \) with the inclusion of Set into Poset. Mildly overloading notation, we denote the composite by \( At : \mathcal{L}_\Sigma^{op} \rightarrow \text{Poset} \).

**Definition 4.** Given functors \( H, K : \mathcal{L}_\Sigma^{op} \rightarrow \text{Poset} \), a lax transformation from \( H \) to \( K \) is the assignment to each object \( n \) of \( \mathcal{L}_\Sigma \), of an order-preserving function \( \alpha_n : Hn \rightarrow Kn \) such that for each map \( f : n \rightarrow m \) in \( \mathcal{L}_\Sigma \), one has \((Kf)(\alpha_m) \leq (\alpha_n)(Hf)\), pictured as follows:

\[
\begin{array}{ccc}
Hm & \xrightarrow{\alpha_m} & Km \\
| & \geq & |
\downarrow & \downarrow & \downarrow \\
Hn & \xrightarrow{\alpha_n} & Kn \\
Kf & &
\end{array}
\]

Functors and lax transformations, with pointwise composition, form a locally ordered category denoted by \( \text{Lax}(\mathcal{L}_\Sigma^{op}, \text{Poset}) \). Such categories and generalisations have been studied extensively, e.g., in [18, 19, 20, 23].

**Definition 5.** Define \( P_f : \text{Poset} \rightarrow \text{Poset} \) by letting \( P_f(P) \) be the partial order given by the set of finite subsets of \( P \), with \( A \leq B \) if for all \( a \in A \), there exists \( b \in B \) for which \( a \leq b \) in \( P \), with behaviour on maps given by image. Define \( P_c \) similarly but with countability replacing finiteness.

We are not interested in arbitrary posets in modelling logic programming, only those that arise, albeit inductively, by taking subsets of a set qua discrete poset. So we gloss over the fact that, for an arbitrary poset \( P \), Definition 5 may yield factoring, with the underlying set of \( P_f(P) \) being a quotient of the set of subsets of \( P \). The potential difficulty is that if Definition 5 makes \( A \leq B \) and \( B \leq A \), then as \( P_f \) is defined in terms of posets, it follows that \( A \) is put equal to \( B \), which would be inconvenient, but in fact, it does not substantially affect us as we start with discrete posets rather than arbitrary ones.

**Example 5.** Modelling Example 1, ListNat generates a lax transformation of the form \( p : At \rightarrow P_f P_f At \) as follows: \( At(n) \) is the set of atomic formulae in ListNat with at most \( n \) variables.

For example, \( At(0) \) consists of \( \text{nat}(0), \text{nat}(\text{nil}), \text{list}(0), \text{list}(\text{nil}), \text{nat}(\text{s}(0)), \text{nat}(\text{s}(\text{nil})), \text{list}(\text{s}(0)), \text{list}(\text{s}(\text{nil})), \text{nat}(\text{cons}(0,0)), \text{nat}(\text{cons}(0,\text{nil})), \text{nat}(\text{cons}(\text{nil},0)), \text{nat}(\text{cons}(\text{nil},\text{nil})), \text{etcetera.} \)
Similarly, \( \text{At}(1) \) includes all atomic formulae containing at most one (specified) variable \( x \), thus all the elements of \( \text{At}(0) \) together with \( \text{nat}(x) \), \( \text{list}(x) \), \( \text{nat}(s(x)) \), \( \text{list}(s(x)) \), \( \text{nat}(\text{cons}(0, x)) \), \( \text{nat}(\text{cons}(x, 0)) \), \( \text{nat}(\text{cons}(x, x)) \), etcetera.

The function \( p_n : \text{At}(n) \rightarrow P_f P_f \text{At}(n) \) sends each element of \( \text{At}(n) \), i.e., each atom \( A(x_1, \ldots, x_n) \) with variables among \( x_1, \ldots, x_n \), to the set of sets of atoms in the antecedent of each unifying substituted instance of a clause in \( P \) with head for which a unifying substitution agrees with \( A(x_1, \ldots, x_n) \).

Taking \( n = 0 \), \( \text{nat}(0) \in \text{At}(0) \) is the head of one clause, and there is no other clause for which a unifying substitution will make its head agree with \( \text{nat}(0) \). The clause with head \( \text{nat}(0) \) has the empty set of atoms as its tail, so \( p_0(\text{nat}(0)) = \{\emptyset\} \).

Taking \( n = 1 \), \( \text{list}(\text{cons}(x, 0)) \in \text{At}(1) \) is the head of one clause given by a unifying substitution applied to the final clause of \( \text{ListNat} \), and accordingly \( p_1(\text{list}(\text{cons}(x, 0))) = \{\{\text{nat}(x), \text{list}(0)\}\} \).

The family of functions \( p_n \) satisfy the inequality required to form a lax transformation because if \( A(x_1, \ldots, x_n) \) is the head of a substituted instance of a clause in \( P \), then so is \( A(t_1, \ldots, t_n) \) for any substitutions \( t_i \) for \( x_i \). The family does not satisfy the strict requirement of naturality as explained in the Introduction.

We now analyse the relationship between a lax transformation \( p : \text{At} \rightarrow P_f P_f \text{At} \) and \( \bar{p} : \text{At} \rightarrow C(P_f P_f) \text{At} \), the corresponding coalgebra for the cofree comonad \( C(P_f P_f) \) on \( P_f P_f \).

We recall the central abstract result of [17], the notion of an “oplax” map of coalgebras being required to match that of lax transformation. Notation of the form \( H\text{-coalg} \) refers to coalgebras for an endofunctor \( H \), while notation of the form \( C\text{-Coalg} \) refers to coalgebras for a comonad \( C \). The subscript \( \text{oplax} \) refers to oplax maps and, given an endofunctor \( E \) on \( \text{Poset} \), the notation \( \text{Lax}(\text{L}_\Sigma^{\text{op}}, E) \) denotes the endofunctor on \( \text{Lax}(\text{L}_\Sigma^{\text{op}}, \text{Poset}) \) given by post-composition with \( E \); similarly for a comonad.

**Theorem 2.** [17] For any locally ordered endofunctor \( E \) on \( \text{Poset} \), if \( C(E) \) is the cofree comonad on \( E \), then there is a canonical isomorphism

\[
\text{Lax}(\text{L}_\Sigma^{\text{op}}, E)\text{-coalg}_{\text{oplax}} \simeq \text{Lax}(\text{L}_\Sigma^{\text{op}}, C(E))\text{-Coalg}_{\text{oplax}}
\]

Theorem 2 tells us that for any endofunctor \( E \) on \( \text{Poset} \), the relationship between \( E \)-coalgebras and \( C(E) \)-coalgebras extends pointwise from \( \text{Poset} \) to \( \text{Lax}(\text{L}_\Sigma^{\text{op}}, \text{Poset}) \) providing one matches lax natural transformations by oplax maps of coalgebras. It follows that, given an endofunctor \( E \) on \( \text{Poset} \) with cofree comonad \( C(E) \), the cofree comonad for the endofunctor on \( \text{Lax}(\text{L}_\Sigma^{\text{op}}, \text{Poset}) \) sending \( H : \text{L}_\Sigma^{\text{op}} \rightarrow \text{Poset} \) to the composite \( EH : \text{L}_\Sigma^{\text{op}} \rightarrow \text{Poset} \) sends \( H \) to the composite \( C(E)H \). Taking the example \( E = P_f P_f \) allows us to conclude the following.

**Corollary 1.** [17] \( \text{Lax}(\text{L}_\Sigma^{\text{op}}, C(P_f P_f)) \) is the cofree comonad on \( \text{Lax}(\text{L}_\Sigma^{\text{op}}, P_f P_f) \).
Corollary 1 means that there is a natural bijection between lax transformations
\[ p : \text{At} \rightarrow P_f P_f \text{At} \]
and lax transformations
\[ \overline{p} : \text{At} \rightarrow C(P_f P_f) \text{At} \]
subject to the two conditions required of a coalgebra of a comonad given pointwise, thus by applying the construction of Theorem 1 pointwise. So it is the abstract result we need in order to characterise the coinductive trees generated by logic programs with no existential variables, extending Theorem 1. As explained in the Introduction, an existential variable in a logic program is a variable that appears in the tail of a clause but not in its head. We explain the situation in detail in Example 6, but for now, just note that ListNat does not have existential variables, so the following result applies directly to it.

**Theorem 3.** Let \( C(P_f P_f) \) denote the cofree comonad on the endofunctor \( P_f P_f \) on Poset. Then, given a logic program \( P \) with no existential variables on \( \text{At} \), defining \( p_n(A(x_1, \ldots, x_n)) \) to be the set of sets of atoms in each antecedent of each unifying substituted instance of a clause in \( P \) with head for which a unifying substitution agrees with \( A(x_1, \ldots, x_n) \), the corresponding \( \text{Lax}(\mathcal{L}_\Sigma^p, C(P_f P_f)) \)-coalgebra \( \overline{p} : \text{At} \rightarrow C(P_f P_f) \text{At} \) sends an atom \( A(x_1, \ldots, x_n) \) to the coinductive tree for \( A(x_1, \ldots, x_n) \).

**Proof.** The absence of existential variables ensures that any variable that appears in the antecedent of a clause must also appear in its head. So every atom in every antecedent of every unifying substituted instance of a clause in \( P \) with head for which a unifying substitution agrees with \( A(x_1, \ldots, x_n) \) actually lies in \( \text{At}(n) \). Moreover, there are only finitely many sets of sets of such atoms. So the construction of each \( p_n \) is well-defined, i.e., the image of \( A(x_1, \ldots, x_n) \) lies in \( P_f P_f \text{At}(n) \). The collection of maps given by \( p_n \) for each object \( n \) of \( \mathcal{L}_\Sigma \) forms a lax transformation from \( \text{At} \) to \( P_f P_f \text{At} \): the laxness condition holds because substitution preserves the truth of a clause, i.e., if one makes a substitution into both the head and tail of a clause that is true, the substituted instance of the clause is also true.

By Corollary 1, \( \overline{p} \) is determined pointwise. So, to construct it, we may fix \( n \) and follow the proof of Theorem 1, consistently replacing \( \text{At} \) by \( \text{At}(n) \). To complete the proof, observe that the construction of \( p \) from a logic program \( P \) matches the construction of the coinductive tree for an atom \( A(x_1, \ldots, x_n) \) if \( P \) has no existential variables. So following the proof of Theorem 1 completes this proof.

**Example 6.** Attempting to model Example 2, that of graph connectedness, GC, by mimicking the modelling of ListNat in Example 5, i.e., defining the function \( p_n : \text{At}(n) \rightarrow P_f P_f \text{At}(n) \) by sending each element of \( \text{At}(n) \), i.e., each atom \( A(x_1, \ldots, x_n) \) with variables among \( x_1, \ldots, x_n \), to the set of sets of atoms in the
antecedent of each unifying substituted instance of a clause in $P$ with head for which a unifying substitution agrees with $A(x_1, \ldots, x_n)$, fails.

Consider the clause

$$\text{connected}(x, y) \leftarrow \text{edge}(x, z), \text{connected}(z, y)$$

Modulo possible renaming of variables, the head of the clause, i.e., the atom $\text{connected}(x, y)$, lies in $A(2)$ as it has two variables. There is trivially only one substituted instance of a clause in $GC$ with head for which a unifying substitution agrees with $\text{connected}(x, y)$, and the singleton set consisting of the set of atoms in its antecedent is $\{\{\text{edge}(x, z), \text{connected}(z, y)\}\}$, which does not lie in $P_f P_f A(2)$ as it has three variables appear in it rather than two. See Section 2 for a picture of the coinductive tree for $\text{connected}(x, y)$.

We dealt with that inelegantly in [17]: in order to force $p_2(\text{connected}(x, y))$ to lie in $P_f P_f A(2)$ and model $GC$ in any reasonable sense, we allowed substitutions for $z$ in $\{\{\text{edge}(x, z), \text{connected}(z, y)\}\}$ by any term on $x, y$ on the basis that there is no unifying such, so we had better allow all possibilities. So, rather than modelling the clause directly, recalling that $A(2) \subseteq A(3) \subseteq A(4)$, etcetera, modulo renaming of variables, we put

$$p_2(\text{connected}(x, y)) = \{\{\text{edge}(x, x), \text{connected}(x, y)\}, \{\text{edge}(x, y), \text{connected}(y, y)\}\}$$

$$p_3(\text{connected}(x, y)) = \{\{\text{edge}(x, x), \text{connected}(x, y)\}, \{\text{edge}(x, y), \text{connected}(y, y)\},\{\text{edge}(x, z), \text{connected}(z, y)\}\}$$

$$p_4(\text{connected}(x, y)) = \{\{\text{edge}(x, x), \text{connected}(x, y)\}, \{\text{edge}(x, y), \text{connected}(y, y)\},\{\text{edge}(x, z), \text{connected}(z, y)\}, \{\text{edge}(x, w), \text{connected}(w, y)\}\}$$

etcetera: for $p_2$, as only two variables $x$ and $y$ appear in any element of $P_f P_f A(2)$, we allowed substitution by either $x$ or $y$ for $z$; for $p_3$, a third variable may appear in an element of $P_f P_f A(3)$, allowing an additional possible substitution; for $p_4$, a fourth variable may appear, etcetera.

Countability arises if a unary symbol $s$ is added to $GC$, as in that case, for $p_2$, not only did we allow $x$ and $y$ to be substituted for $z$, but we also allowed $s^n(x)$ and $s^n(y)$ for any $n > 0$, and to do that, we replaced $P_f P_f$ by $P_f$, allowing for the countably many possible substitutions.

Those were inelegant decisions, but they allowed us to give some kind of model of all logic programs. We shall revisit this in Section 6.

Theorem 3 models the coinductive trees generated by ListNat as the latter has no existential variables, but for $GC$, as explained in Example 6, the natural construction of $p$ did not model the clause

$$\text{connected}(x, y) \leftarrow \text{edge}(x, z), \text{connected}(z, y)$$

directly, and so its extension a fortiori could not model the coinductive trees generated by $\text{connected}(x, y)$.

For arbitrary logic programs, the way we defined $p(A(x_1, \ldots, x_n))$ in earlier papers such as [1] was in terms of a variant of the coinductive tree generated by $A(x_1, \ldots, x_n)$ in two key ways:
1. coinductive trees allow new variables to be introduced as one passes down the tree, e.g., with

\[
\text{connected}(x, y) \leftarrow \text{edge}(x, z), \text{connected}(z, y)
\]

appearing in it. However, because of the presence of the variable \(z\), the set \(\{\{\text{edge}(x, z), \text{connected}(z, y)\}\}\) does not appear in \(P_f P_f At(2)\). In previous papers, we made clumsy adaptations of the natural model in order to model the clause.

2. coinductive trees are finitely branching, as one expects in logic programming, but in previous papers, we allowed \(p(A(x_1, \ldots, x_n))\) to be infinitely branching in order to model the countably many possible applications of a unary function symbol.

5. Saturated semantics for logic programs

Bonchi and Zanasi’s saturated semantics approach to modelling logic programming in [14] was to consider \(P_f P_f\) as we did in [17], sending \(At\) to \(P_f P_f At\), but to ignore the inherent laxness, replacing \(\text{Lax}(\mathcal{L}_\Sigma^\text{op}, \text{Poset})\) by \([\text{ob}(\mathcal{L}_\Sigma), \text{Set}]\), where \(\text{ob}(\mathcal{L}_\Sigma)\) is the set of objects of \(\mathcal{L}_\Sigma\) treated as a discrete category, i.e., as a category containing only identity maps. Their central construction may be seen in a more axiomatic setting as follows.

For any small category \(C\), let \(\text{ob}(C)\) denote the discrete subcategory with the same objects as \(C\), with inclusion \(I : \text{ob}(C) \rightarrow C\). Then the functor

\[
[I, \text{Set}] : [C, \text{Set}] \rightarrow [\text{ob}(C), \text{Set}]
\]

has a right adjoint given by right Kan extension, and that remains true when one extends from \(\text{Set}\) to any complete category, and it all enriches, e.g., over \(\text{Poset}\) [3]. As \(\text{ob}(C)\) has no non-trivial arrows, the right Kan extension is a product, given by

\[
(ran_I H)(c) = \prod_{d \in C} H d^{C(c, d)}
\]

By the Yoneda lemma, to give a natural transformation from \(K\) to \((ran_I H)(\cdot)\) is equivalent to giving a natural, or equivalently in this setting, a “not necessarily natural”, transformation from \(KI\) to \(H\). Taking \(C = \mathcal{L}_\Sigma^\text{op}\) gives exactly Bonchi and Zanasi’s formulation of saturated semantics [14].

It was the fact of the existence of the right adjoint, rather than its characterisation as a right Kan extension, that enabled Bonchi and Zanasi’s constructions of saturation and desaturation, but the description as a right Kan extension informed their syntactic analysis.

Note for later that products in \(\text{Poset}\) are given pointwise, so agree with products in \(\text{Set}\). So if we replace \(\text{Set}\) by \(\text{Poset}\) here, and if \(C\) is an ordinary category without any non-trivial \(\text{Poset}\)-enrichment, the right Kan extension
would yield the same set as above, with an order on it determined by that on \( H \).

In order to unify saturated semantics with lax semantics, we need to rephrase Bonchi and Zanasi’s formulation a little. Upon close inspection, one can see that, in their semantics, they only used objects of \([\text{ob}(\Sigma), \text{Set}]\), equivalently \([\text{ob}(\Sigma), \text{Set}]\), of the form \( HI \) for some \( H : \Sigma^{op} \rightarrow \text{Set} \) [14]. That allows us, while making no substantive change to their body of work, to reformulate it a little, in axiomatic terms, as follows.

Let \([C, \text{Set}]_d\) denote the category of functors from \( C \) to \( \text{Set} \) and “not necessarily natural” transformations between them, i.e., a map from \( H \) to \( K \) consists of, for all \( c \in C \), a function \( \alpha_c : Hc \rightarrow Kc \), without demanding a naturality condition. The functor \([I, \text{Set}] : [C, \text{Set}] \rightarrow [\text{ob}(C), \text{Set}]\) factors through the inclusion of \([C, \text{Set}]_d\) into \([C, \text{Set}]_d\) as follows:

\[
[C, \text{Set}] \xrightarrow{J_{\text{Set}}} [C, \text{Set}]_d \xrightarrow{J'} [\text{ob}(C), \text{Set}]
\]

The functor \( J' : [C, \text{Set}]_d \rightarrow [\text{ob}(C), \text{Set}]\) sends a functor \( H : C \rightarrow \text{Set} \) to the functor \( HI : \text{ob}(C) \rightarrow \text{Set} \). The composite \([I, \text{Set}] = J'J_{\text{Set}}\) has a right adjoint given by right Kan extension, and \( J'\) is fully faithful. By elementary category theory [33], it follows that \( J_{\text{Set}} : [C, \text{Set}] \rightarrow [C, \text{Set}]_d\) has a right adjoint that sends \( H : C \rightarrow \text{Set} \) to the right Kan extension of \( J'(H) = HI \) along \( I \).

Thus one can rephrase Bonchi and Zanasi’s work to assert that the central mathematical fact that supports saturated semantics is that the inclusion

\[
[\Sigma^{op}, \text{Set}] \rightarrow [\Sigma^{op}, \text{Set}]_d
\]

has a right adjoint that sends a functor \( H : \Sigma^{op} \rightarrow \text{Set} \) to the right Kan extension \( \text{ran}_I HI \) of the composite \( HI : \text{ob}(\Sigma)^{op} \rightarrow \text{Set} \) along the inclusion \( I : \text{ob}(\Sigma) \rightarrow \Sigma \).

We can now unify lax semantics with saturated semantics by developing a precise body of theory that relates the inclusion

\[
J_{\text{Set}} : [C, \text{Set}] \rightarrow [C, \text{Set}]_d
\]

which has a right adjoint that sends \( H : C \rightarrow \text{Set} \) to \( \text{ran}_I HI \), with the inclusion

\[
J : [C, \text{Poset}] \rightarrow \text{Lax}(C, \text{Poset})
\]

which also has a right adjoint, that right adjoint being given by a restriction of the right Kan extension \( \text{ran}_I HI \) of the composite \( HI : \text{ob}(C) \rightarrow \text{Poset} \) along the inclusion \( I : \text{ob}(C) \rightarrow C \).

The existence of the right adjoint follows from Theorem 3.13 of [19], but we give an independent proof here and a description of it in terms of right Kan extensions in order to show that Bonchi and Zanasi’s explicit constructions of saturation and desaturation apply equally in this setting.

Consider the inclusions

\[
[C, \text{Poset}] \rightarrow \text{Lax}(C, \text{Poset}) \rightarrow [C, \text{Poset}]_d
\]
Exactly as for Set as above, for any small category $C$, the inclusion

$$J_{\text{Poset}} : [C, \text{Poset}] \to [C, \text{Poset}]_d$$

has a right adjoint sending $H : C \to \text{Poset}$ to $\text{ran}_1 HI$. In order to give a right adjoint to $J : [C, \text{Poset}] \to \text{Lax}(C, \text{Poset})$, we will restrict $\text{ran}_1 HI$ to a subfunctor $R(H)$ in $[C, \text{Poset}]$ so that to give a natural transformation from $K$ into the restriction $R(H)$ of $\text{ran}_1 HI$ is equivalent to giving a map from $K$ to $H$ in $\text{Lax}(C, \text{Poset})$, i.e., a map in $[C, \text{Poset}]_d$ that satisfies the condition that, for all $f : c \to d$, one has $Hf.\alpha_c \leq \alpha_d.Kf$. This can be done by defining $R(H)$ to be an inserter, which is a particularly useful kind of limit that applies to locally ordered categories and is a particular kind of generalisation of the notion of equaliser.

**Definition 6.** [19] Given parallel maps $f, g : X \to Y$ in a locally ordered category $D$, an inserter from $f$ to $g$ is an object $\text{Ins}(f, g)$ of $D$ together with a map $i : \text{Ins}(f, g) \to X$ such that $fi \leq gi$ and is universal such, i.e., for any object $Z$ and map $z : Z \to X$ for which $fz \leq gz$, there is a unique map $k : Z \to \text{Ins}(f, g)$ such that $ik = z$. Moreover, for any such $z$ and $z'$ for which $z \leq z'$, then $k \leq k'$, where $k$ and $k'$ are induced by $z$ and $z'$ respectively.

An inserter is a form of limit. Taking $D$ to be $\text{Poset}$, the poset $\text{Ins}(f, g)$ is given by the full sub-poset of $X$ determined by $\{x \in X | f(x) \leq g(x)\}$. Being limits, inserters in functor categories are determined pointwise.

The inserter we require is subtle, in the spirit of the work of [19] and [3]. Given a functor $H : C \to \text{Poset}$, we define a parallel pair of maps in $[C, \text{Poset}]$, i.e., natural transformations, $\delta_1$ and $\delta_2$. Their domains and codomains, which must be functors from $C$ to $\text{Poset}$, are given as follows:

$$\delta_1, \delta_2 : \prod_{d \in C} H(d)^{C(\cdot, d)} \to \prod_{d, d' \in C} H(d)^{C(\cdot, d) \times C(d, d')}$$

i.e., the domain of both $\delta_1$ and $\delta_2$ is the functor from $C$ to $\text{Poset}$ that sends $c$ to $\prod_{d \in C} H(d)^{C(c, d)}$, and similarly for the codomain.

Using the property of products, to give such natural transformations is equivalent, via Currying, to giving, for each $c, d$ and $d'$ in $C$, maps of the form

$$(\delta_1)(d, d') : C(c, d) \times C(d, d') \times \prod_{d \in C} H(d)^{C(c, d)} \to H(d')$$

natural in $c$. We define the two maps as follows:

1. The $(d, d')$-component of $\delta_1 c$ is determined by composing

$$\circ_c \times \text{id} : C(c, d) \times C(d, d') \times \prod_{d \in C} H(d)^{C(c, d)} \to C(c, d') \times \prod_{d \in C} H(d)^{C(c, d)}$$

with the evaluation of the product at $d'$, i.e., taking the $d'$-th component of the product and applying evaluation to $C(c, d') \times H(d)^{C(c, d')}$. 

20
2. the \((d, d')\)-component of \(\delta_2 c\) is determined by evaluating the product at \(d\)

\[
C(c, d) \times C(d, d') \times \prod_{d \in C} H^d C(c, d) \rightarrow C(d, d') \times H d
\]

then composing with

\[
C(d, d') \times H d \xrightarrow{H \times \text{id}} H d^d H d \times H d \xrightarrow{\text{eval}} H d'
\]

**Theorem 4.** The right adjoint \(R\) to the inclusion \(J : [C, \text{Poset}] \rightarrow \text{Lax}(C, \text{Poset})\) sends \(H : C \rightarrow \text{Poset}\) in \(\text{Lax}(C, \text{Poset})\) to the inserter in \([C, \text{Poset}]\) from \(\delta_1\) to \(\delta_2\)

\[
\delta_1, \delta_2 : (\text{ran}_1 HI)(-) = \prod_{d \in C} H^d C(-, d) \rightarrow \prod_{d, d' \in C} H^d C(-, d) \times C(d, d')
\]

Although the statement of the theorem is complex, the proof is routine, along similar lines to proofs in [3]. One simply needs to check that \(\delta_1\) and \(\delta_2\) are natural, which they routinely are, and that the inserter satisfies the universal property we seek, which it does by construction.

**Corollary 2.** Let \(R\) be the right adjoint to the inclusion \(J : [C, \text{Poset}] \rightarrow \text{Lax}(C, \text{Poset})\). Then, for any functor \(H : C \rightarrow \text{Poset}\) in \(\text{Lax}(C, \text{Poset})\), the functor \(R(H) : C \rightarrow \text{Poset}\) is a subfunctor in \([C, \text{Poset}]\) of the right Kan extension, \(\text{ran}_1 HI\), of \(HI\) along the inclusion \(I : \text{ob}(C) \rightarrow C\).

The inclusion of \(R(H)\) into \(\text{ran}_1 HI\) is given by the canonical map from the inserter that defines \(R(H)\) in the statement of Theorem 4 into \(\text{ran}_1 HI\), the domain of \(\delta_1\) and \(\delta_2\).

Bonchi and Zanasi’s saturation and desaturation constructions remain exactly the same: the saturation of \(p : At \rightarrow P_f P_f At\) is a natural transformation \(\bar{p} : At \rightarrow \text{ran}_1 P_f P_f At I\) that factors through \(\text{Ins}(\delta_1, \delta_2)\) without any change whatsoever to its construction, that being so because of the fact of \(p\) being lax.

With this result in hand, it is routine to work systematically through Bonchi and Zanasi’s papers, using their saturation and desaturation constructions exactly as they had them, without discarding the inherent laxness that logic programming, cf data refinement, possesses.

So this unifies lax semantics, which flows from, and may be seen as an instance of, Tony Hoare’s semantics for data refinement [21, 22, 23], with saturated semantics and its more denotational flavour [6].

6. Lax semantics for logic programs refined: existential variables

In Section 4, following [17], we gave lax semantics for logic programs without existential variables, such as ListNat. In particular, we modelled the coinductive trees they generate. Restriction to non-existential examples such as ListNat is
common for implementational reasons [1, 11, 12, 13], so Section 4 allowed the modelling of coinductive trees for a natural class of logic programs.

Nevertheless, we would like to model coinductive trees generated by logic programming in full generality, including examples such as that of GC. We need to refine the lax semantics of Section 4 in order to do so, and, having just unified lax semantics with saturated semantics in Section 5, we would like to retain that unity in making such a refinement. So that is what we do in this section.

We initially proposed such a refinement in the workshop paper [25] that this paper extends, but since the workshop, we have found a further refinement that strengthens the relationship with the modelling of local state [26]. So our constructions here are a little different to those in [25].

In order to model coinductive trees, it follows from Example 6 that the endofunctor $L^{op} \rightarrow \text{Poset}$ that sends $\text{At}$ to $P_f P_f \text{At}(2)$ as it involves three variables $x$, $y$ and $z$. In general, we need to allow the image of $p_n$ to lie in the set given by applying $P_f P_f$ to a superset of $\text{At}(n)$, one that includes $\text{At}(m)$ for all $m \geq n$. In Example 6, that would allow the image of $p_2$ to lie in $P_f P_f \text{At}(3)$ rather than in $P_f P_f \text{At}(2)$, thus allowing us to map $\text{connected}(x, y)$ to $\{\{\text{edge}(x, z), \text{connected}(z, y)\}\}$ as desired.

However, we do not want to double-count: there are six injections of 2 into 3, inducing six inclusions $\text{At}(2) \subseteq \text{At}(3)$, and one only wants to count each atom in $\text{At}(2)$ once. So we refine $P_f P_f \text{At}(n)$ to become $P_f P_f(\int \text{At}(n))$, where $\int \text{At}$ is defined as follows.

Letting $\text{Inj}$ denote the category of natural numbers and injections, for any Lawvere theory $L$, there is a canonical identity-on-objects functor $J: \text{Inj}^{op} \rightarrow L$.

**Definition 7.** We define $\int \text{At}(n)$ to be the colimit of the composite functor

$$n/\text{Inj} \xrightarrow{\text{cod}} \text{Inj} \xrightarrow{J} L^{op} \xrightarrow{\text{At}} \text{Poset}$$

This functor sends an injection $j: n \rightarrow m$ to $\text{At}(m)$, with the $j$-th component of the colimiting cocone being of the form $\rho_j: \text{At}(m) \rightarrow \int \text{At}(n)$.

The colimiting property is precisely the condition required to ensure no double-counting (see [33] or, for the enriched version, [3] of this construction in a general setting). Intuitively, the colimit amounts to taking the sum over all $m \geq n$ of $\text{At}(m)$, subject to identification along the lines of fixing an inclusion of $\text{At}(k)$ into $\text{At}(m)$ if $m \geq k \geq n$, but one needs care in regard to coherence of inclusions with respect to each other: the category theory is smoother if one simply defines the construction to be the colimit.

It is not routine to extend the construction of $\int \text{At}(n)$ to a functor from $L^{op}$ to $\text{Poset}$. To do so, we mimic the construction on arrows used to define the monad for local state in [26]. We first used this idea in [25] and we refine
our use of it in this paper to make for a closer technical relationship with the
semantics of local state in \[26\]: we do not fully understand the relationship yet,
but there seems considerable potential based on the work here to make precise
comparison between the role of variables in logic programming with that of
worlds in modelling local state.

In detail, the definition of \(\int \mathcal{A}_\Sigma\) extends canonically to become a functor
\(\int \mathcal{A}_\Sigma : L^{\text{op}} \Sigma \rightarrow \text{Poset}\) that sends a map \(f : n \rightarrow n'\) in \(L \Sigma\) to the order-preserving
function

\[
\int At(f) : \int At(n') \rightarrow \int At(n)
\]
determined by the colimiting property of \(\int At(n')\) as follows.

For each \(j' : n' \rightarrow l \in n'/\text{Inj}\), there is a unique natural number \(k\) and an
isomorphism between \(l\) and \(n' + k\), such that composite of \(j'\) with the isomor-
phism is the canonical injection from \(n'\) to \(n' + k\). So, in calculating with the
colimit, we may identify \(j'\) with the canonical injection from \(n'\) to \(n' + k\). So \(j'\)
induces a cocone

\[
\begin{array}{ccc}
\text{At}(n' + k) & \xrightarrow{At(f + k)} & \text{At}(n + k) \\
\downarrow{\rho_j} & & \downarrow{\rho} \\
\int \text{At}(n) & & \\
\end{array}
\]

where \(j : n \rightarrow n + k\) is the canonical injection of \(n\) into \(n + k\). It is routine to
check that this assignment respects composition and identities, thus is functorial.

There is nothing specific about the functor \(\text{At} : \mathcal{L}_{\Sigma}^{\text{op}} \rightarrow \text{Poset}\) in the above
construction. The construction generalises without fuss from defining the func-
tor \(\int \mathcal{A}_\Sigma : L^{\text{op}} \Sigma \rightarrow \text{Poset}\) to the definition of \(\int H : \mathcal{L}_{\Sigma}^{\text{op}} \rightarrow \text{Poset}\) for any functor
\(H : \mathcal{L}_{\Sigma}^{\text{op}} \rightarrow \text{Poset}\).

In order to make each map \(\alpha : H \Rightarrow K\) generate a map \(\int \alpha : \int H \Rightarrow \int K\), we
need to specify in exactly what category we treat \(H\) as an object. \(\text{Lax}(\mathcal{L}_{\Sigma}^{\text{op}}, \text{Poset})\)
is not possible because \(\int H(n)\) is defined to be a (strict rather than lax) col-
limit, so a (strict) cocone into \(\int K(n)\) is required in order to generate the map
\(\int \alpha(n) : \int H(n) \rightarrow \int K(n)\). We would have that if we had strict naturality
of \(\alpha\) with respect to injections, but that is not true of an arbitrary map \(\alpha\) in
\(\text{Lax}(\mathcal{L}_{\Sigma}^{\text{op}}, \text{Poset})\). So we refine \(\text{Lax}(\mathcal{L}_{\Sigma}^{\text{op}}, \text{Poset})\) by restricting its maps in order
to do that.

We accordingly restrict the maps of \(\text{Lax}(\mathcal{L}_{\Sigma}^{\text{op}}, \text{Poset})\) to allow only those lax
transformations \(\alpha : H \Rightarrow K\) that are strict with respect to maps in \(\text{Inj}\), i.e.,
those \(\alpha\) such that for any injection \(i : n \rightarrow m\), the diagram

\[
\begin{array}{ccc}
Hn & \xrightarrow{\alpha_n} & Kn \\
\downarrow{Hi} & & \downarrow{Ki} \\
Hm & \xrightarrow{\alpha_m} & Km
\end{array}
\]
commutes. A restriction of this nature is standard in 2-category theory, e.g.,
in [19], as one typically needs to distinguish between lax and strict maps, with
strict commutativity only in regard to the latter.

Summarising this discussion yields the following:

**Definition 8.** Let \( \text{Lax}_{\Sigma}^{\text{op}}(\mathcal{L}^\Sigma, \text{Poset}) \) denote the category with objects given
by functors from \( \mathcal{L}^\Sigma \) to \( \text{Poset} \), maps given by lax transformations that strictly
respect injections, and composition given pointwise.

**Proposition 2.** cf [26] Let \( J: \text{Inj}^{\text{op}} \rightarrow \mathcal{L}^\Sigma \) be the canonical inclusion. Define \( \int: \text{Lax}_{\Sigma}^{\text{op}}(\mathcal{L}^\Sigma, \text{Poset}) 
\rightarrow \text{Lax}_{\Sigma}^{\text{op}}(\mathcal{L}^\Sigma, \text{Poset}) \)
on objects as above. Given \( \alpha: H \Rightarrow K \) in \( \text{Lax}_{\Sigma}^{\text{op}}(\mathcal{L}^\Sigma, \text{Poset}) \), define \( \int \alpha(n) \) by the fact that \( j \in n/\text{Inj} \) is coherently isomorphic to the canonical inclusion \( j: n \rightarrow n + k \) for a unique natural number \( k \), and applying the definition of \( \int \) \( H(n) \) as a colimit to the cocone given by composing \( \alpha_{n+k}: H(m) = H(n + k) \rightarrow K(n + k) = K(m) \)
with the canonical map \( K(m) \rightarrow \int K(n) \) exhibiting \( \int K(n) \) as a colimit. Then \( \int(\_\_) \) is an endofunctor on \( \text{Lax}_{\Sigma}^{\text{op}}(\mathcal{L}^\Sigma, \text{Poset}) \).

The proof is routine, albeit after lengthy calculation involving colimits.

We can now model an arbitrary logic program by a map \( p: \text{At} \rightarrow \text{Pf} \int \text{At} \)in \( \text{Lax}_{\Sigma}^{\text{op}}(\mathcal{L}^\Sigma, \text{Poset}) \), modelling ListNat as we did in Example 5 but now modelling the clauses of GC directly rather than using the awkward substitution instances of Example 6.

**Example 7.** Except for the restriction of \( \text{Lax}(\mathcal{L}^\Sigma, \text{Poset}) \) to \( \text{Lax}_{\Sigma}^{\text{op}}(\mathcal{L}^\Sigma, \text{Poset}) \), ListNat is modelled in exactly the same way here as it was in Example 5, the reason being that no clause in ListNat has a variable in the tail that does not already appear in the head. We need only observe that, although \( p \) is not strictly natural in general, it does strictly respect injections. For example, if one views \( \text{list}(\text{cons}(x, 0)) \) as an element of \( \text{At}(2) \), its image under \( p_2 \) agrees with its image under \( p_1 \).

**Example 8.** In contrast to Example 6, using \( \text{Pf} \int \) \( \text{At} \), we can emulate the construction of Examples 5 and 7 for ListNat to model GC.

Modulo possible renaming of variables, \( \text{connected}(x, y) \) is an element of \( \text{At}(2) \). The function \( p_2 \) sends it to the element \( \{\{\text{edge}(x, z), \text{connected}(z, y)\}\} \) of \( (\text{Pf} \int \text{At})(2) \). This is possible by taking \( n = 2 \) and \( m = 3 \) in Definition 7. In contrast, \( \{\{\text{edge}(x, z), \text{connected}(z, y)\}\} \) is not an element of \( \text{Pf} \int \text{At}(2) \), hence the failure of Example 6.

The behaviour of \( \text{Pf} \int \text{At} \) on maps ensures that the lax transformation \( p \) strictly respects injections. For example, if \( \text{connected}(x, y) \) is seen as an element of \( \text{At}(3) \), the additional variable is treated as a fresh variable \( w \), so does not affect the image of \( \text{connected}(x, y) \) under \( p_3 \).
Theorem 5. The functor $P_f P_f \int : \text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^{\text{op}}, \text{Poset}) \to \text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^{\text{op}}, \text{Poset})$ induces a cofree comonad $C(P_f P_f \int)$ on $\text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^{\text{op}}, \text{Poset})$. Moreover, given a logic program $P$ qua $P_f P_f \int$-coalgebra $p : \text{At} \to P_f P_f \int \text{At}$, the corresponding $C(P_f P_f \int)$-coalgebra $\overline{p} : \text{At} \to C(P_f P_f \int)(\text{At})$ sends an atom $A(x_1, \ldots, x_n) \in \text{At}(n)$ to the coinductive tree for $A(x_1, \ldots, x_n)$.

Proof. If one restricts $P_f P_f \int$ to $[\text{Inj}, \text{Poset}]$, there is a cofree comonad on it for general reasons, $[\text{Inj}, \text{Poset}]$ being locally finitely presentable and $P_f P_f \int$ being an accessible functor [32]. However, as we seek a little more generality than that, and for completeness, we shall construct the cofree comonad.

We first show that $P_f P_f \int$, restricted to $[\text{Inj}, \text{Poset}]$, preserves monomorphisms. Monomorphisms in $[\text{Inj}, \text{Poset}]$ are given pointwise. For any functor $H : \text{Inj} \to \text{Poset}$ and any natural number $n$, $\{H\}(n)$ is given by taking an $\omega$-directed colimit $\text{colim}_{m \geq n} H(m)$ relative to a canonical choice of inclusions, and quotienting by structural permutations. An $\omega$-directed colimit respects monomorphisms, and given a natural inclusion of $H$ into $K$, if the images of two elements of $\{H\}(n)$ are equal in $\{K\}(n)$, a permutation $\theta$ in $\text{Inj}$ generates the equality. By naturality, $H(\theta)$ yields equality between the two elements. Thus $\int$ preserves monomorphisms.

Thus $[\text{Inj}, \text{Poset}]$ is accessible and $P_f P_f \int$ is accessible and preserves monomorphisms, and so we may apply Corollary 3.3 of [32] to obtain a description of the cofree comonad in terms of limits.

Observe that products in the category $\text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^{\text{op}}, \text{Poset})$ are given pointwise, with pointwise projections. Moreover, those projections are strictly natural, as explained in Proposition 2.1 and Remark 2.9 of [19].

We can describe the cofree comonad $C(P_f P_f \int)$ on $\text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^{\text{op}}, \text{Poset})$ pointwise as the same limit as in the proof of Theorem 1, similarly to Theorem 3. In particular, replacing $\text{At}$ by $\text{At}(n)$ and replacing $P_f P_f \int$ by $P_f P_f \int$ in the diagram in the proof of Theorem 1, one has

$$\ldots \to \text{At}(n) \times (P_f P_f \int)(\text{At}) \to \text{At}(n) \times (P_f P_f \int)(\text{At}) \to \text{At}(n)$$

with maps determined by the projection $\pi_0 : \text{At}(-) \times (P_f P_f \int)(\text{At}) \to \text{At}(-)$, with the endofunctor $P_f P_f \int$ applied to it. For any $n$, $C(P_f P_f \int)(\text{At})(n)$ is the limit, potentially transfinite, of the diagram [32, Corollary 3.3].

Because the projections are strictly natural, and because $\int$ and $P_f$ send strictly natural transformations to strictly natural transformations, the limiting property determines, for each map $f : n \to m$ in $\mathcal{L}_\Sigma$, a map of posets from $C(P_f P_f \int)(\text{At})(m)$ to $C(P_f P_f \int)(\text{At})(n)$. The unicity property of the limit ensures that this construction makes $C(P_f P_f \int)(\text{At})$ into a functor from $\mathcal{L}_\Sigma^{\text{op}}$ to $\text{Poset}$.

The construction and proof apply equally to an arbitrary functor $H : \mathcal{L}_\Sigma^{\text{op}} \to \text{Poset}$ in $\text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^{\text{op}}, \text{Poset})$ as they do to $\text{At}$, yielding the construction of $C(P_f P_f \int)(\text{H})$ in general.
A map in $Lax_{Inj}(\mathcal{L}_\Sigma^{op}, \mathbf{Poset})$ is a lax transformation $\alpha : H \Rightarrow K$ that is strictly natural with respect to injections. The data for any such map, i.e., the collection of poset maps $\alpha(n)$, is fully determined by its restriction to a map in $[Inj, \mathbf{Poset}]$. So applying the limiting property of $[32, \text{Corollary 3.3}]$, the data for $C(P_f P_f \dashv)(\alpha) : C(P_f P_f \dashv)(H) \Rightarrow C(P_f P_f \dashv)(K)$ is determined and satisfies the properties required of an endofunctor on $[Inj, \mathbf{Poset}]$. It agrees with the universal property of the limit defining $C(P_f P_f \dashv)(H)(n)$. It follows from the universal property, specifically its two-dimensional property (see, for instance, the proof of $[19, \text{Proposition 2.1}]$) that $C(P_f P_f \dashv)(\alpha)$ is lax natural with regard to arbitrary maps in $\mathcal{L}_\Sigma$.

Thus we have defined $C(P_f P_f \dashv)$ as an endofunctor on $Lax_{Inj}(\mathcal{L}_\Sigma^{op}, \mathbf{Poset})$. The counit and comultiplication of $C(P_f P_f \dashv)$ are also constructed by restricting to $[Inj, \mathbf{Poset}]$, using the classical result for the strict setting $[32]$, then using the two-dimensional property of the limit to verify coherence in regard to arbitrary maps in $\mathcal{L}_\Sigma$.

The construction of $p$ is given pointwise, with it following from its coinductive construction that it yields the coinductive trees as required: because of our construction of $\int At$ to take the place $At$ in Theorem 3, the image of $p$ lies in $P_f P_f \int At$.

The lax naturality in respect to general maps $f : m \rightarrow n$ means that a substitution applied to an atom $A(x_1, \ldots, x_n) \in At(n)$, i.e., application of the function $At(f)$ to $A(x_1, \ldots, x_n)$, followed by application of $\overline{p}$, i.e., taking the coinductive tree for the substituted atom, or application of the function $(C(P_f P_f \dashv)At)f$ to the coinductive tree for $A(x_1, \ldots, x_n)$ potentially yield different trees: the former substitutes into $A(x_1, \ldots, x_n)$, then takes its coinductive tree, while the latter applies a substitution to each node of the coinductive tree for $A(x_1, \ldots, x_n)$, then prunes to remove redundant branches.

**Example 9.** Extending Example 8, consider $\text{connected}(x, y) \in At(2)$. In expressing $GC$ as a map $p : At \rightarrow P_f P_f \int At$ in Example 8, we put

$$p_2(\text{connected}(x, y)) = \{\{\text{edge}(x, z), \text{connected}(z, y)\}\}$$

Accordingly, $p_2(\text{connected}(x, y))$ is the coinductive tree for $\text{connected}(x, y)$, thus the infinite tree generated by repeated application of the same clause modulo renaming of variables.

If we substitute $x$ for $y$ in the coinductive tree, i.e., apply the function $(C(P_f P_f \dashv)At)(x, x)$ to it (see the definition of $L_\Sigma$ at the start of Section 4 and observe that $(x, x)$ is a 2-tuple of terms, thus an arrow from 1 to 2), we obtain the same tree but with $y$ systematically replaced by $x$. However, if we substitute $x$ for $y$ in $\text{connected}(x, y)$, i.e., apply the function $At(x, x)$ to it, we obtain $\text{connected}(x, x) \in At(1)$, whose coinductive tree has additional branching as the first clause of $GC$, i.e., $\text{connected}(x, x) \leftarrow$ may also be applied.

In contrast to this, we have strict naturality with respect to injections: for example, an injection $i : 2 \rightarrow 3$ yields the function $At(i) : At(2) \rightarrow At(3)$ that, modulo renaming of variables, sends $\text{connected}(x, y) \in At(2)$ to itself seen as...
an element of \( \text{At}(3) \), and the coinductive tree for \( \text{connected}(x, y) \) is accordingly also sent by \( (C(P_f P_f f)\text{At})(i) \) to itself seen as an element of \( (C(P_f P_f f)\text{At})(3) \).

Example 9 illustrates why, although the condition of strict naturality with respect to injections holds for \( P_f P_f f \), it does not hold for \( \text{Lax}(\mathcal{L}_\Sigma^\text{op}, P_f P_f) \) in Example 6 as we did not model the clause

\[
\text{connected}(x, y) \leftarrow \text{edge}(x, z), \text{connected}(z, y)
\]

directly there, but rather modelled all substitution instances into all available variables.

Turning to the relationship between lax semantics and saturated semantics given in Section 5, we need to refine our construction of the right adjoint to the inclusion

\[
[\mathcal{L}_\Sigma^\text{op}, \text{Poset}] \to \text{Lax}(\mathcal{L}_\Sigma^\text{op}, \text{Poset})
\]

to give a construction of a right adjoint to the inclusion

\[
[\mathcal{L}_\Sigma^\text{op}, \text{Poset}] \to \text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^\text{op}, \text{Poset})
\]

As was the case in Section 5, such a right adjoint exists for general reasons as an example of the main result of [19]. An explicit construction of it arises by emulating the construction of Theorem 4. In the statement of Theorem 4, putting \( C = \mathcal{L}_\Sigma^\text{op} \), we described a parallel pair of maps in \( [\mathcal{L}_\Sigma^\text{op}, \text{Poset}] \) and constructed their inserter, the inserter being exactly the universal property corresponding to the laxness of the maps in \( \text{Lax}(\mathcal{L}_\Sigma^\text{op}, \text{Poset}) \). Here, we use the same technique but with equaliser replacing inserter, to account for the equalities in \( \text{Lax}_{\text{Inj}}(C, \text{Poset}) \). Thus we take an equaliser of two variants of \( \delta_1 \) and \( \delta_2 \) seen as maps in \( [\mathcal{L}_\Sigma^\text{op}, \text{Poset}] \) with domain \( \text{Ins}(\delta_1, \delta_2) \)

Again, one may use the same constructions of saturation and desaturation as before, i.e., use a right Kan extension. However, now, instead of applying the right Kan extension to \( P_c P_f \) as in [2], one may apply it to \( P_f P_f f \text{At} \). This still generates countability as application of the right Kan extension generates countability, but the saturation construction is now applied to an inherently finitary map, \( p : \text{At} \to P_f P_f f \text{At} \), rather than to a map with countability already built into it. So our account of existential variables allows a refinement, albeit a subtle one, to saturated semantics, in addition to refining lax semantics.

7. Semantics for variables in logic programs: local variables

The relationship between the semantics of logic programming we propose here and that of local state is yet to be explored fully, and we leave the bulk of it to future work. However, as explained in Section 6, the definition of \( f \) was informed by the semantics for local state in [26], and we have preliminary results that strengthen the relationship.
Proposition 3. The endofunctor \( \int (-) \) on \( \text{Lax}_{\text{Inj}}(\mathcal{L}_\Sigma^\text{op}, \text{Poset}) \) canonically supports the structure of a monad, with unit \( \eta_H : H \Rightarrow \int H \) defined, at \( n \), by the id\(_n\) component \( \rho_{\text{id}_n} : Hn \rightarrow \int Hn \) of the colimiting cocone, and with multiplication \( \mu_H : \int \int H \Rightarrow \int H \) defined, at \( n \), by observing that if \( m = n + k \) and \( p = m + l \), then \( p = n + (k + l) \) with canonical injections \( j_k \), \( j_l \) and \( j_{k+l} \) coherent with each other, and applying the doubly indexed colimiting property of \( \int \int \) to \( \rho_{j_{k+l}} : H(p) \rightarrow \int H(n) \).

This bears direct comparison with the monad for local state in the case where one has only one value, as studied by Stark [34]. The setting is a little different. Stark does not consider maps in \( \mathcal{L}_\Sigma \) or laxness, and his base category is \( \text{Set} \) rather than \( \text{Poset} \). However, if one restricts our definition of \( \int \) and the other data for the monad of Proposition 3 to \([\text{Inj}, \text{Set}]\), one obtains Stark’s construction.

The monad for local state in [26] also extends Stark’s construction but in a different direction: for local state, neither \( \text{Inj} \) nor \( \text{Set} \) is extended, but state, which is defined by a functor into \( \text{Set} \) is interpolated into the definition of the functor \( \int \), which restricts to \([\text{Inj}, \text{Set}])\). That interpolation of state is closely related to our application of \( P_f P_f \) to \( \int \): just as the former gives rise to a monad for local state on \([\text{Inj}, \text{Set}]\), the latter bears the ingredients for a monad as follows.

Proposition 4. For any endofunctor \( P \) on \( \text{Set} \), here is a canonical distributive law

\[
\int P(-) \rightarrow P \int (-)
\]

of the endofunctor \( P \circ - \) over the monad \( \int \) on \([\text{Inj}, \text{Set}]\).

The canonicity of the distributive law arises as \( \int \) is defined pointwise as a colimit, and the distributive law is the canonical comparison map determined by applying \( P \) pointwise to the colimiting cone defining \( \int \).

The functor \( P_f P_f \) does not quite satisfy the axioms for a monad [35] (see also [2]), but variants of \( P_f P_f \), in particular \( P_f M_f \), where \( M_f \) is the finite multiset monad on \( \text{Set} \), do [35] (also see [2]). Putting \( P = P_f M_f \), the distributive law of Proposition 4 respects the monad structure of \( P_f M_f \), yielding a canonical monad structure on the composite \( P_f M_f \int \).

The full implications of that are yet to be investigated, but, trying to emulate the analysis of local state in [26], we believe we have a natural set of operations and equations that generate the monad \( P_f M_f \int \). That encourages us considerably towards the possibility of seeing the semantics for logic programming, both lax and saturated, as an example of a general semantics of local effects. We have not yet fully understood the significance of the specific combination of operations and equations generating the monad, but we are currently investigating it.
8. Conclusions and Further Work

Let $P_f$ be the covariant finite powerset functor on $Set$. Then, to give a variable-free logic program $P$ is equivalent to giving a $P_f P_f$-coalgebra structure $p : At \longrightarrow P_f P_f At$ on the set $At$ of atoms in the program. Now let $C(P_f P_f)$ be the cofree comonad on $P_f P_f$. Then, the $C(P_f P_f)$-coalgebra $\overline{p} : At \longrightarrow C(P_f P_f) At$ corresponding to $p$ sends an atom to the coinductive tree it generates. This fact is the basis for both our lax semantics and Bonchi and Zanasi’s saturated semantics for logic programming.

Two problems arise when, following standard category theoretic practice, one tries to extend this semantics to model logic programs in general by extending from $Set$ to $[\mathcal{L}_\Sigma^\text{op}, Set]$, where $\mathcal{L}_\Sigma$ is the free Lawevere theory generated by a signature $\Sigma$. The first is that the natural construction $p : At \longrightarrow P_f P_f At$ does not form a natural transformation, so is not a map in $[\mathcal{L}_\Sigma^\text{op}, Set]$.

Two resolutions were proposed to that: lax semantics [1], which we have been developing in the tradition of semantics for data refinement [21], and saturated semantics [2], which Bonchi and Zanasi have adopted. In this paper, we have shown that the two resolutions are complementary rather than competing, the first modelling the theorem-proving aspect of logic programming, while the latter models proof search.

In modelling theorem-proving, lax semantics led us to identify and develop the notion of coinductive tree. To express the semantics, we extended $[\mathcal{L}_\Sigma^\text{op}, Set]$ to $\text{Lax}(\mathcal{L}_\Sigma^\text{op}, \text{Poset})$, the category of strict functors and lax transformations between them. We followed standard semantic practice in extending $P_f$ from $Set$ to $\text{Poset}$ and we postcomposed the functor $At : \mathcal{L}_\Sigma^\text{op} \longrightarrow \text{Poset}$ by $P_f P_f$. Bonchi and Zanasi also postcomposed $At$ by $P_f P_f$, but then saturated. We showed that their saturation and desaturation constructions are generated exactly by starting from $\text{Lax}(\mathcal{L}_\Sigma^\text{op}, \text{Poset})$ rather than from $[\text{ob}(\mathcal{L}_\Sigma)^\text{op}, Set]$ as they did, thus unifying the underlying mathematics of the two developments, supporting their computational coherence.

The second problem mentioned above relates to existential variables, those being variables that appear in the antecedent of a clause but not in its head. The problem of existential clauses is well-known in the literature on theorem proving and within communities that use term-rewriting, TM-resolution or their variants. In TRS [29], existential variables are not allowed to appear in rewriting rules, and in type inference, the restriction to non-existential programs is common [31]. In logic programming, the problem of handling existential variables when constructing proofs with TM-resolution marks the boundary between its theorem-proving and problem-solving aspects.

Existential variables are not present in many logic programs, but they do occasionally occur in important examples, such as those developed by Sterling and Shapiro [27]. The problem for us was that, in the presence of existential variables, the natural model $p : At \longrightarrow P_f P_f At$ of a logic program might escape its codomain, i.e., $p_n (A)$ might not lie in $P_f P_f At(n)$ because of the new variables. On one hand, we want to model them, but on the other, the fact of the difficulty for us means that we have semantically identified the concept
of existential variable, which is positive.

In this paper, we have resolved the problem by refining \( Lax(L^{\mathsf{op}}_\Sigma, \mathsf{Poset}) \) to \( Lax_{\text{Inj}}(L^{\mathsf{op}}_\Sigma, \mathsf{Poset}) \), insisting upon strict naturality for injections, and by refining the construction \( P_f P_f At \) to \( P_f P_f \int At \), thus allowing for additional variables in the tail of a clause in a logic program. That has allowed us to model coinductive trees for arbitrary logic programs, in particular those including existential variables. We have also considered the effect of such refinement on saturated semantics, where the right Kan extension generates countability but use of \( P_c \) is no longer required.

In order to refine \( P_f P_f (\_\_\_) \), we followed a technique developed in the semantics of local state [26]. That alerted us to the relationship between variables in logic programming with the use of worlds in modelling local state. So, as ongoing work, we are now relating our semantics for logic programming with that for local state. For the future, we shall continue to develop that, with the hope of being able to locate our semantics of logic programming within a general semantics for local effects.

Beyond that, a question that we have not considered semantically at all yet but which our applied investigations are encouraging is that of modelling recursion. There are fundamentally two kinds of recursion that arise in logic programming as there may be recursion in terms and recursion in proofs. For example, \( \text{stream} (\text{scons}(x, y)) \leftarrow \text{stream}(y) \) is a standard (co-)recursive definition of infinite streams in logic programming literature. More abstractly, the following program \( P_1: p(f(x)) \leftarrow p(x) \) defines an infinite data structure \( p \) with constructor \( f \). For such cases, proofs given by coinductive trees will be finite. An infinite sequence of (finite) coinductive trees will be needed to approximate the intended operational semantics of such a program, as we discuss in detail in [1, 36]. In contrast, there are programs like \( P_2: p(x) \leftarrow p(x) \) or \( P_3: p(x) \leftarrow p(f(x)) \) that are also recursive, but additionally their proofs as given by coinductive trees will have an infinite size.

In [37, 38] programs like \( P_1 \) were called productive, for producing (infinite) data, and programs like \( P_2 \) and \( P_3 \) — non-productive, for recursing without producing substitutions. The productive case amounts to a loop in the Lawvere theory \( L_\Sigma \) [39], while the non-productive case amounts to repetition within a coinductive tree, possibly modulo a substitution. This paper gives a close analysis of trees. That should set the scene for investigation of recursion, as it seems likely to yield more general kinds of graph that arise by identifying loops in \( L_\Sigma \) and by equating nodes in trees.

The lax semantics we presented here has recently inspired investigations into the importance of TM-resolution (as modelled by the coinductive trees) in programming languages. In particular, TM-resolution is used in type class inference in Haskell [31]. In [13, 40] we showed applications of nonterminating TM-resolution in Haskell type classes. We plan to continue looking for applications of this work in programming language design beyond logic programming.
