Title: Removal of antiretroviral drugs stavudine and zidovudine in water under UV254 and UV254/H2O2 processes: quantum yields, kinetics and ecotoxicology assessment

Article Type: Research Paper

Keywords: photodegradation; microreactor; mutagenicity and genotoxicity; water reuse; antiretroviral

Abstract: The concentration of antiretroviral drugs in wastewater treatment plants (WWTP) effluents and surface waters of developed and developing countries, especially in the African region more affected by HIV, has increased significantly in recent years due to their widespread use. The presence of antiretroviral in natural water bodies limits the possibility of reuse of such waters, after traditional disinfection process (i.e. UV, chlorine) for civil and irrigation purposes. The removal of stavudine and zidovudine under UV254 or UV254/H2O2 irradiation was investigated in distilled water. The quantum yield of direct photolysis and the kinetic constant of reaction of hydroxyl radical with the antiretrovirals at different pH have been evaluated. A battery of ecotoxicological tests (i.e. inhibition growth, bioluminescence, mutagenic and genotoxic activity) using different living organisms belonging to bacteria (Aliivibrio fischeri, Salmonella typhimurium), crustacean (Dapnia magna) and algae (Raphidocelis subcapitata) revealed a marked influence of the UV dose absorbed by the solution during the photolytic processes on the ecotoxic activity.

*Journal of Hazardous Materials*

Dear Editor,

please find enclosed a copy of the original manuscript: “Removal of antiretroviral drugs stavudine and zidovudine in water under UV$_{254}$ and UV$_{254}$/H$_2$O$_2$ processes: quantum yields, kinetics and ecotoxicology assessment” by Danilo Russo, Antonietta Siciliano, Marco Guida, Roberto Andreozzi, Nuno M. Reis, Gianluca Li Puma and Raffaele Marotta, which we submit to JHM.

The proposed manuscript has not been published or presented elsewhere in part or in entirety, and is not under consideration by another Journal. All the Authors have approved the proposal and agree with submission of the manuscript to JHM. There are no conflicts of interest to declare.

**Word count (text and captions without references): 4980**

Thank you for your consideration. We look forward to hearing from you.

Sincerely

Napoli, 12/08/2017

*The Authors*
Novelty

We present for the first time a kinetic and ecotoxicological investigation on the removal with \( \text{UV}_{254} \)-assisted processes of two antiretrovirals (stavudine and zidovudine) from milli-Q water through a microphotoreactor, which allows very fast experimentation with minimal sample volumes. Zidovudine and stavudine are new emerging poor biodegradable microcontaminants detected in STP effluents and surface waters, especially in African countries, due to the highest incidence of HIV-positive people. Recently, the level of zidovudine in Kenian surface waters increased up to three order of magnitude. Moreover, these substances have been demonstrated to exert a carcinogenic activity. For this purpose, the ecotoxicity of solutions was evaluated to assess genotoxicity and mutagenicity.
Removal of antiretroviral drugs stavudine and zidovudine in water under UV$_{254}$ and UV$_{254}$/H$_2$O$_2$ processes: quantum yields, kinetics and ecotoxicology assessment

1. Introduction

In the last decades, as a result of the widespread availability of pharmaceutical drugs, occurrence, identification, quantification, removal and environmental fate of these emerging contaminants have received significant critical attention [1-3]. Among this new and increasingly growing class of water microcontaminants, the presence of antiretroviral drugs (ARVs) in wastewater and surface water has been the focus of recent research [4-9]. Since their introduction into the market in the early 90s, ARVs have rapidly spread across the world
because of their effectiveness in the treatment of the HIV virus [10]. In fact, ARVs inhibit the reverse transcriptase of the HIV virus, repressing viral replication [11]. The most commonly used ARVs include zidovudine (ZDV), stavudine (STV), lamivudine, abacavir and nevirapine which are usually administered as a combination therapy to increase their effectiveness in preventing HIV reproduction [12]. ZDV was the first marketed antiretroviral [12] and is still one of the most widely used. STV is also one of the most common ARVs, despite presenting several side effects, because of its relatively low price [13]. Collectively, ARVs increase the life expectancy of HIV-positive patients, however, significant concerns have been raised about their simultaneous release to the environment [4,5,9]. New concerns are also related to their consumption in the illicit drugs nyaope [14] and whoonga [15]. As a result, STV and ZDV have been often detected in effluents of wastewater treatment plants (WWTPs) and in natural surface water, in Europe and in Africa, at levels of tens of ng·L⁻¹ up to hundreds of ng·L⁻¹ (Table 1).

In Europe, the main ARVs contamination route of natural waters is through human body excretion and subsequent release in the sewage system [9]. The further presence of ARVs in the effluents of WWTPs and surface water demonstrates the inefficiency of current WWTPs treatment methods. The highest concentrations have been detected in Kenya and South Africa. The levels of ZDV and STV in these African countries, have been shown to be higher in surface water compared to WWTPs effluents, which contrast with the general trend in Europe. The level of ZDV in Kenian surface waters increased up to three order of magnitude during the period 2012 to 2016 [16,18]. Recently, ZDV has also been detected in groundwater [16] which can be probably ascribed to the illicit use and direct spillage in water.

It has been reported [7] that ZDV is not completely removed in conventional treatment plants, a conclusion also shown for an aerobic and anaerobic WWTP in Germany [9].
although, these authors reported 68% of ZDV removal in different German WWTP with an activated sludge system. Further biological treatment studies performed in synthetic wastewater demonstrated that ZDV is non biodegradable, toxic, and inhibitory to activated sludge bacteria [22]. Higher removals have been reported for STV through activated sludge (> 78%) and biological treatment (> 89%) [7,9]. Even though the reported LC50 (Daphnid acute 48 h) are 980 mg·L⁻¹ and higher than 100 mg·L⁻¹ for STV and ZDV respectively [23-25], synergistic and mutagenic effects on the aquatic fauna and humans cannot be ruled out. For example, ZDV has been demonstrated to have carcinogenic potential [26]. Advanced oxidation processes (AOPs) have increasingly been proposed as effective tertiary treatments for the removal of biorecalcitrant emerging contaminants [27,28]. Among these, the UV254/H2O2 is considered one of the most convenient process since it can be simply applied in existing municipal water treatment plants adopting UV254 lamps for water disinfection, such as treatment plants for water reuse and tertiary units in conventional STP [29]. Notably, reclaimed water reuse for irrigation is especially suitable in water stressed areas [30], which often also present the highest incidence of HIV-positive people, such as Central and South Africa. In spite of the apparent effectiveness of AOPs in micropollutants removal, the potential for the formation of highly toxic by-products [31,32] calls for longer treatment times and for the further evaluation of the ecotoxicity of the treated water. In this study the kinetics of ZDV and STV direct photolysis under UV254 radiation and in the presence of hydrogen (UV254/H2O2) was investigated in order to estimate important photo-kinetic parameters, such as the quantum yields and the second-order kinetic constant of reaction between OH radicals and the compounds, which are necessary for design and retrofitting of water treatment plants. The reaction kinetics were investigated by means of a recent developed methodology which used microcapillary photoreactor systems [33], previously adopted for the investigation of the photolytic kinetics of other micropollutants [34-36]. The
use of this new microphotoreactor technology has been shown to be particularly suitable for the study on highly priced, hazardous, or poorly available water contaminants since it allows to run the entire experimental campaign using minimal amount of compounds, in this case less than 50 mg of ZDV and STV.

The implementation of water reclamation systems and of the environmental risks posed by the effluents, requires comprehensive ecotoxicological assessment on a set of biological tests on species at different trophic levels [37]. For this purpose, the three most frequently ecotoxicity bioassays in aquatic systems are the assessment on *Aliivibrio fischeri* and *Daphnia magna* tests for acute toxicity and the *Raphidocelis subcapitata* test for chronic toxicity. Although these target organisms have often been used to assess the impact of contaminated water, the main focus of water quality testing should also concern organisms-dependent chemical-physical and biological properties of the target molecules. In particular, several studies have demonstrated that ARVs differ in genotoxic potency, chromosomal damage and aberration types induced *in vitro* and in perinatally exposed mice and infants [38-40].

In consequence, in the present study we investigated the ecotoxicity of untreated and treated solutions of ZDV and STV using a battery of ecologically relevant testing species to assess the acute and chronic toxicities and genotoxicity and mutagenicity.

2. Experimental

2.1. Materials

Zidovudine (> 99%), stavudine (> 98%), NaOH (≥ 98%), H2SO4 (98%), hydrogen peroxide (30% in H2O), acetonitrile (≥ 99.9%), methanol (≥ 99.9%), phosphoric acid (85% in H2O), catalase from Micrococcus lysodeikticus, CaCl2·2H2O(≥ 99.5%), MgSO4·7H2O (≥ 98%), NaHCO3 (≥ 99.5 %), KCl (≥ 99 %), NH4Cl (≥ 99.9%), MgCl2·6H2O (≥ 98%), KH2PO4(≥
99%), FeCl$_3$·6H$_2$O (≥ 98%), Na$_2$EDTA·2H$_2$O (≥ 99.9%), H$_3$BO$_3$ (≥ 99%), MnCl$_2$·4H$_2$O (≥ 98%), ZnCl$_2$ (≥ 99%), CoCl$_2$·6H$_2$O (≥ 98%), Na$_2$MoO$_4$·2H$_2$O (≥ 98%) and CuCl$_2$·2H$_2$O (≥ 98%) were all purchased from Sigma-Aldrich and used as received.

Reconstitution solution, osmotic adjusting solution (OAS) and diluent (NaCl 2%) were the reagents used for the *Aliivibrio fischeri* toxicity test (Strategic diagnostics Inc. SDI). All the reacting solutions were prepared adding the contaminants and hydrogen peroxide to milliQ water. When necessary, pH was adjusted by using dilute aqueous solutions of NaOH and H$_2$SO$_4$.

### 2.2. Photolytic treatments

A microcapillary film (MCF) array photoreactor was used to perform the UV$_{254}$ photolysis and UV$_{254}$/H$_2$O$_2$ experiments. A detailed description and a scheme of the reactor can be found elsewhere [33,34]. Briefly, the polymeric film microreactor consists of ten tubular microcapillaries (Lamina Dielectrics Ltd, Billingshurst, West Sussex, UK) with a mean hydraulic diameter of 195 µm and an average optical path length of 152 µm. The MFC was fed by means of a syringe pump (HA Harvard Apparatus PHD Ultra) and wrapped around a germicidal lamp (Germicidal G8T5, Ge Lighting) emitting at 254 nm. The nominal lamp power could be varied from 8.0 to 4.5 W with the use of a switch power supplier. The emitted photon fluxes per unit volume ($I_0/V$) were estimated by hydrogen peroxide actinometry [41,42] and were $1.92 \cdot 10^{-2}$ ein·s$^{-1}$·L$^{-1}$ and $1.27 \cdot 10^{-2}$ ein·s$^{-1}$·L$^{-1}$, respectively. The residence time (space time) through the MFC was varied changing the length of the film exposed to the light. Samples were collected at the outlet of the MFC after reaching steady state conditions, and rapidly analyzed by HPLC. Negligible temperature differences (~25°C) between the inlet and the outlet samples were found in all the experiments. All the experimental runs were
carried out in duplicate. The entire experimental campaign (> 50 runs) was carried out using about 2500 ml of distilled water.

In order to produce relatively larger volumes of treated solutions, necessary to run the ecotoxicology tests, experiments were also carried out in a thermostated (25 °C) stirred glass batch annular photoreactor with a volume of $4.8 \times 10^{-1}$ L, housing a low pressure mercury lamp emitting at 254 nm (Helios Italquartz, HGL10T5L, 17 W) in the centre axis of the annulus. In both photoreactor devices, ZDV and STV solutions at an initial concentration of 4.5 mg·L⁻¹ and 4.35 mg·L⁻¹ respectively, were treated without and with the addition of hydrogen peroxide (molar ratio $\text{H}_2\text{O}_2$/ARV = 100) and with a UV254 dose corresponding to treatment times or space times necessary to achieve a 45% and 90% conversion of the antiretrovirals and for space times double those needed to achieve a complete conversion. The UV254 dose (mJ·cm⁻²) was calculated as the average photon fluence rate multiplied by the treatment time (s). The average photon fluence rate emitted by the UV lamp at 254 nm was 4.7 mW·cm⁻² (UVC DELTA OHM radiometer). The experimental device was described elsewhere [36].

Catalase enzyme was also added to both treated and untreated solutions to determine the ecotoxicological effects without the interference given by the presence of $\text{H}_2\text{O}_2$ residuals.

2.3. Analytical methods

ZDV, STV, and hydrogen peroxide concentrations were measured by HPLC (1100 Agilent) equipped with a Gemini 5u C6-Phenyl (260 x 4.60 mm) (Phenomenex) column. An isocratic method was used for the simultaneous quantification of ZDV and hydrogen peroxide with mobile phase (0.8 mL·min⁻¹) made of 93% aqueous phosphoric acid (10 mM) and 7% acetonitrile. Under these analytical conditions the retention times of hydrogen peroxide and ZDV were 4.1 and 13.7 min, respectively. The mobile phase was changed to 80% water and
20% methanol for the simultaneous identification of H$_2$O$_2$ and STV with retention times of 3.7 and 10 min, respectively. The signals were acquired at 266 nm.

The molar absorption coefficients of STV and ZDV were estimated using a Perkin Elmer UV/VIS spectrometer (mod. Lambda 35).

2.4. Ecotoxicological methods

2.4.1. Toxicity test with Daphnia magna

The test was conducted in accordance with ISO 6341 [43]. Every test was performed in quadruplicate with four control groups. Briefly, neonates aged less than 24 hours were separated into four groups and exposed to different concentrations of untreated and treated solutions of ZDV and STV. All tests were carried out at constant temperature (20±2 °C) and in darkness and organisms were not fed during the experiments. After 48 h exposure, daphnids that were not able to swim within 15 seconds under gentle agitation were considered to be immobilized.

2.4.2. Bacteria toxicity test

The Microtox® SPT procedure [44] was used to evaluate the acute toxicity of the samples using as endpoint the bioluminescence inhibition of the naturally emitted by A. fischeri (strain NRRL-B-11177) after a contact time of 30 min with the test sample. The samples were serially diluted to a series of four concentrations, then a volume of 10 μL of reconstituted bacterial reagent was added to dilutions series of samples. The emission of bioluminescence was recorded after 30 min of contact time with the bacteria at 15±2 °C.
2.4.3. Algal growth inhibition test with Raphidocelis subcapitata

The growth inhibition test was assessed following the ISO 8692:2012 standard procedure [45]. Exponentially growing algae (10^4 cell·mL^{-1}) were exposed to various concentrations of the test samples in six replicates over a period of 72 h under defined conditions, as described elsewhere [46]. Growth and inhibition were quantified from measurements of the algal biomass density (cell counts) as a function of time. The specific growth rate of *R. subcapitata* in each replicate culture was calculated from the logarithmic increase in cell density in the intervals from 0 to 72 h using the following equation: \( \mu = \frac{\ln N_n - \ln N_0}{t_n - t_0} \), where \( N_0 \) is the cell concentration at \( t = 0 \), \( N_n \) the final cell concentration after 72 h of exposure, \( t_0 \) the time of start measurement, and \( t_n \) the time of last measurement (hours from start). The results were expressed as the mean (± standard deviation) of the percentage inhibition of the cell growth (% I) of the sample compared with the negative control (p≤0.05).

2.4.4. Mutagenicity assay with Salmonella typhimurium

The Muta-Chromoplate kit was used to evaluate the mutagenicity [47]. The fluctuation tests were performed using *S. typhimurium* strains TA100 and observing the potential *his*- reverse mutation after exposure to mutagens [48].

Bacteria cultures, grown overnight and reaching the exponential growth phase, were exposed for 5 days at 37° C to different samples concentrations, in a liquid medium into 96-well microtiter plates. After this period, the positives samples wells that turned yellow were counted, while the purple wells were considered as negatives. The reversion of mutants (*his* +) exhibited the yellow color due to the acidification of the test medium resulting from the growth of reverse mutants. The number of *his*+ revertant colonies in each sample was determined as a mean value of the three plates. The results were expressed as a mutagenicity ratio (MR), i.e. the ratio of the number of *S. typhimurium* revertants grown in the presence of
the tested sample to the number of spontaneously appeared revertants. The sample was considered mutagenic when \( MR \geq 2 \) [49]. \( \chi \)-square analysis was used for statistical evaluation of the treated plates versus the control plates.

2.4.5. Genotoxicity assay with *Salmonella typhimurium*

The umu test [50] was performed according to standard procedure [51], which was developed for the detection of genotoxic materials that cause DNA cell damage. In this assay, a modified strain of *S. typhimurium* TA1535/pSK 1002 bacteria was used, whereby a \( \beta \)-galactosidase gene was linked to SOS-DNA response. Bacterial cultures were grown overnight at 37 °C and then diluted in TGA medium (Tryptone-Glucose-Ampicillin medium) until the cells entered the logarithmic growth phase. The cells were then exposed to the test samples for 2 hours. The induction of genotoxicity (expressed as \( \beta \)-galactosidase activity) was determined colorimetrically at 420 nm after adding o-nitrophenyl galactopyranoside to the samples. Growth was measured as the absorbance at a wavelength of 600 nm. The result was calculated as an induction ratio, \( IR = (1/G) \times US \), where \( G \) was the growth and \( US \) the relative enzyme activity. The sample was considered genotoxic when \( IR \) was greater than 1.5. The significance of the differences between the mean values of different tests and controls was assessed by Student’s test and analysis of variance (ANOVA) with a 0.05 significance level. Moreover, post-hoc analysis were carried out by Tukey’s test [52].

3. Results and Discussion

3.1. Absorbance spectra

The absorbance spectra of ZDV (Fig. 1a) and STV (Fig. 1b) at pH 4.0, 6.5 and 8.0 showed invariance in the pH range from 4.0 to 8.0 for ZDV and from 6.5- to 8.0 for STV. Since pH did not affect ZDV and STV degradation kinetics in the pH ranges 4.0-8.0 and 6.0-8.0,
respectively, the reaction kinetics were investigated in the slightly acidic to alkaline pH range from 6.0 to 8.0, which also is more environmentally relevant. The estimated molar absorption coefficients at 254 nm are summarized in Table 2.

3.2. ZDV and STV direct photolysis and quantum yield estimation

The quantum yield ($\phi_i^{254}$) of direct photolysis at 254 nm was determined with different sets of experimental runs carried out in the MCF varying the ARV initial concentration, the pH and the lamp power (Table 3). The degradation of the generic ARV by direct photolysis follows the mass balance (eq. 1):

$$\frac{dC_i}{dt} = -\frac{l_0}{V} \cdot \phi_i^{254} \cdot \left(1 - \exp(-2.3 \cdot l \cdot \varepsilon_i^{254} \cdot C_i)\right) \quad (1)$$

where $C_i$ is the concentration of ARV, $l_0/V$ is the photon flux per unit volume, $l$ is the average optical length of the reactor (see Photolytic treatments section), and $\varepsilon_i^{254}$ the molar absorption coefficient of the ARV species (Table 2). A Matlab optimization routine based on the Runge-Kutta method was adopted to determine the value of $\phi_i^{254}$ which minimized the objective function (optimisation mode):

$$\sum_{j}^{m} \sum_{i}^{n} (y_{j,i} - c_{j,i})^2 \quad (2)$$

where $c$ and $y$ are the experimental and calculated concentrations at different reaction times ($n$) and experimental runs ($m$). Table 3 shows the estimated quantum yields and the 97% interval of confidence of ZDV and STV. The results corroborate with the previous photolytic decomposition investigation [53], that reported higher sensitivity of ZDV to UVA light compared to STV, with a fluorescent irradiation source in the wavelength spectra from 320 nm to 400 nm.

All the adopted experimental runs used for the kinetic modeling along with the experimental conditions and the average standard deviation are reported in Table 4 whereas Fig. 2 (a-d)
show representative examples of the comparison between the experimental and the calculated profiles for ARV degradation by direct photolysis. As reported, the model was validated simulating simultaneously different experimental runs not included in the optimization routine (simulation mode, Fig. 2e-f).

3.3. Kinetic modeling of UV\textsubscript{254}/H\textsubscript{2}O\textsubscript{2} process

The second order rate constant \( k_{OH,i} \) of the reaction between ZDV and STV with hydroxyl radicals was estimated from a set of experimental runs carried out in the MCF at varying pH, lamp power and \( C_{H_2O_2}/C_i \) molar ratio (Table 5). They were modeled according to the following simplified reaction scheme:

\[
\begin{align*}
H_2O_2 & \xrightarrow{\phi_{H_2O_2}^{254}} 2HO^* & \phi_{H_2O_2}^{254} = 18.6 \text{ M}^{-1} \cdot \text{cm}^{-1} \ [54] \\
ARV & \xrightarrow{\phi_i^{254}} S & (\text{estimated in this work}) \\
ARV + HO^* & \xrightarrow{k_{OH,i}} P & (\text{estimated in this work}) \\
P + HO^* & \xrightarrow{k_{OH,i}} P' & (\text{estimated in this work}) \\
P + HO^* & \xrightarrow{k_{OH,i}} P'' & (\text{estimated in this work}) \\
S + HO^* & \xrightarrow{k_{OH,i}} S' & (\text{estimated in this work}) \\
H_2O_2 + HO^* & \xrightarrow{k_H} HO_2^* + H_2O & k_H = 2.7 \cdot 10^7 \text{M}^{-1} \cdot \text{s}^{-1} \ [55] \\
2HO_2^* & \xrightarrow{k_\ell} O_2 + H_2O_2 & k_\ell = 8.3 \cdot 10^5 \text{M}^{-1} \cdot \text{s}^{-1} \ [56]
\end{align*}
\]

Hydroxyl radicals formed by direct photolysis of hydrogen peroxide under UV\textsubscript{254} radiation (\( r_1 \)) attack the ARV (\( r_3 \)), the P and S pseudo by-products formed (\( r_4-r_5 \)), and the oxidant hydrogen peroxide which generates hydroperoxyl radicals (\( r_6 \)). The latter recombine according to the termination reaction (\( r_7 \)) to form H\textsubscript{2}O\textsubscript{2}. The simultaneous photolysis of ARV is considered in reaction (\( r_2 \)). Assuming that hydroxyl radicals attack both substrate and the first generation of chemical intermediates with the same rate constant \( k_{OH,i} \) and that at any
reaction time the sum of the unconverted substrate ($C_i$) and its by-products ($C_{P,S}$) concentration is equal to the initial antiretroviral concentration ($C_o$):

$$C_o = C_i + C_{P,S}$$

the concentrations of hydroxyl and hydroperoxyl radicals, under the steady state approximation equal:

$$[HO^*]_{ss} = \frac{2F_{H_2O_2}}{k_{OH,i} \cdot C_o + k_H \cdot C_{H_2O_2}}$$

(3)

$$[HO_2^*]_{ss}^2 = \frac{F_{H_2O_2} \cdot k_H \cdot C_{H_2O_2}}{k_l (k_{OH,i} \cdot C_o + k_H \cdot C_{H_2O_2})}$$

(4)

where

$$F_{H_2O_2} = \frac{l_0}{V} \cdot \phi_{H_2O_2}\cdot \left(1 - \exp \left(-2.3 \cdot l \cdot (\varepsilon_{H_2O_2}^{254} \cdot C_{H_2O_2} + \varepsilon_i^{254} \cdot C_i)\right)\right) \frac{\varepsilon_{H_2O_2}^{254} \cdot C_{H_2O_2}}{\varepsilon_{H_2O_2}^{254} \cdot C_{H_2O_2} + \varepsilon_i^{254} \cdot C_i}$$

(5)

and the concentration of $H_2O_2$ and ARVs versus time can be determined by solving the following material balance:

$$\frac{dC_{H_2O_2}}{dt} = -F_{H_2O_2} - \frac{k_H \cdot C_{H_2O_2} \cdot F_{H_2O_2}}{k_{OH,i} \cdot C_o + k_H \cdot C_{H_2O_2}}$$

(6)

$$\frac{dC_i}{dt} = -F_l - \frac{2k_{OH,i} \cdot C_l \cdot F_{H_2O_2}}{k_{OH,i} \cdot C_o + k_H \cdot C_{H_2O_2}}$$

(7)

where

$$F_l = \frac{l_0}{V} \cdot \phi_{l}^{254} \cdot \left(1 - \exp \left(-2.3 \cdot l \cdot (\varepsilon_{H_2O_2}^{254} \cdot C_{H_2O_2} + \varepsilon_i^{254} \cdot C_i)\right)\right) \frac{\varepsilon_{H_2O_2}^{254} \cdot C_{H_2O_2} + \varepsilon_i^{254} \cdot C_i}{\varepsilon_{H_2O_2}^{254} \cdot C_{H_2O_2} + \varepsilon_i^{254} \cdot C_i}$$

(8)

Similarly to the previous analysis, the equations (6-7) were solved by means of an optimization routine to minimize the objective function

$$\sum_{h=1}^{2} \sum_{j}^{m} \sum_{i}^{n} (y_{j,i} - c_{j,i})^2$$

(9)
slightly modified to account for the number of reacting species \((h)\). Selected experimental
runs were not included in the optimization procedure to validate the kinetic model without
further adjustment of the estimated kinetic parameter \(k_{OH,i}\). All the runs adopted, along with
their average standard deviation, are summarized in Table 5. Figure 3 shows the comparisons
between the experimental and calculated data, both in optimization and simulation modes.
The second order rate constant of ARVs investigated with hydroxyl radicals is shown in
Table 6. The kinetic constant of reaction of hydroxyl radical with ZDV, determined by the
competition kinetics method, in literature varies over a wide range: \((1.3 \pm 0.026) \times 10^{10} \text{M}^{-1}\text{s}^{-1}\)
determined using para-chlorobenzoic acid as reference compound \([57]\) and \((5.73 \pm 0.76) \times 10^{9} \text{M}^{-1}\text{s}^{-1}\) determined using acetophenone as reference substance \([17]\). These values are
significant higher than the results obtained in this study. One possible explanation for this
discrepancy is that the competition kinetics method is only reliable if the contribution of
direct photolysis of the investigated compound is absent or negligible. In the absence of that,
the \(k_{OH,i}\) value tends to be overestimated \((k'_{OH,i})\) since it also accounts for the contribution of
direct photolysis to the degradation. To further clarify this aspect, the competition kinetic
method using benzoic acid (BA) as reference compound \([58]\) was also used to estimate the
second order rate constant of hydroxyl radicals with ARVs. According to this method the
\(k'_{OH,i}\) value can be calculated according to (10):

\[
\ln \frac{C_i}{C_o} = \frac{k'_{OH,i}}{k_{OH,BA}} \ln \frac{C_{BA}}{C_{BA_0}}
\]

where \(C_{BA}\) and \(C_{BA_0}\) are the unconverted and initial concentration of benzoic acid, and
\(k_{OH,BA}\) the kinetic constant of reaction between benzoic acid and hydroxyl radical \((5.9 \times 10^9 \text{M}^{-1}\text{s}^{-1} [55])\). Duplicate experimental runs were carried out under the following conditions:

\[\begin{align*}
C_{ZDV_o} &= 2.46 \times 10^{-5} \text{M},
C_{BA_0} &= 2.62 \times 10^{-5} \text{M},
C_{H_2O_2o} &= 1.41 \times 10^{-3} \text{M},
C_{STV_o} &= 2.21 \times 10^{-5} \text{M},
C_{BAo} &= 2.15 \times 10^{-5} \text{M},
C_{H_2O_2o} &= 9.8 \times 10^{-4} \text{M}.
\end{align*}\]

Plotting \(\ln C_i/C_o\) vs \(\ln C_{BA}/C_{BA_0}\), \(k'_{OH,i}\) was estimated as
6.39·10^9 M^{-1} s^{-1} and 5.33·10^9 M^{-1} s^{-1} for ZDV and STV, respectively. As expected both values overestimate the results reported in Table 6. Moreover, the difference is higher for ZDV, in agreement with the higher significance of direct photolysis in the degradation of this compound compared to STV. It is also important to notice that the k'_{DH,ZDV} value estimated in the present study, adopting the competition kinetics method, was within those reported in the literature [17,57].

3.4. Ecotoxicological assessment

The inhibition of A. fischeri luminescence and D. magna immobility was not observed on untreated and UV_{254} or UV_{254}/H_2O_2 treated solutions (data not shown). The growth inhibition of algae R. subcapitata exposed to ZDV and STV containing solutions before and during the photolytic processes (UV_{254} or UV_{254}/H_2O_2) is shown in Figures 4a-f. A marked different trend in effects on algae growth according to the dose–response correlation was observed. ZDV inhibited slightly algal growth, while STV had insignificant effect (less than 20%). The toxicity of the treated solutions in both processes slightly increased increasing the UV dose, also for treatment times corresponding to the complete removal of the antiretroviral drugs. In particular, the inhibited algal growth for the ZDV treated solutions increased by 36% and 44% when the conversion of ZDV was 90% and 100% respectively in both UV_{254} and UV_{254}/H_2O_2 treatments (Fig. 4a). The same increasing trend of ecotoxicity was observed with the STV treated solutions, although the increase in ecotoxicity to R. subcapitata was less significant in comparison to the ZDV treated solutions. The inhibition was 20% and 30% when the STV conversions was 90% and 100% respectively (Fig. 4b).

The antiretroviral drugs showed marked algae growth activity when the dilution factor of untreated and treated solutions was increased from 1:10 (Figs. 4c-d) to 1:100 (Figs. 4e-f), which appeared to stimulate algal growth with a statistically significant extent. This
uncommon “apparently beneficial effect” observed at low doses, known as hormesis, has
been previously reported for some bioindicators such as crustaceans [59,60] and plants and
algae [61] in the presence of nitrogen-containing organic molecules (trinitrotoluene, triazine
herbicides, etc.) such as are STV and ZDV.

Tables 7 and 8 summarize the mutagenicity and genotoxicity results. Both antiretrovirals
were not able to determine a significant SOS system induction, while variability among the
mutagenic responses was observed in the Salmonella mutagenicity assay (threshold value:
2.0). The mutagenicity results indicated that (i) potential mutagenic degradation intermediates
could have been formed at significant levels during the photolysis of ZDV than STV, (ii) the
mutagenicity of the samples further increased at increasing UV$_{254}$ doses and (iii) the
UV$_{254}$/H$_2$O$_2$ treatment produced less mutagenic intermediate products than those formed
during UV$_{254}$ photolysis. Residual mutagenic activity was also observed on the ZDV samples
treated by UV$_{254}$ photolysis for conversions higher than 90%, after a 1:1000 dilution (Table
7). It is useful to point out that the concentration of ZDV in these samples was of the same
order of magnitude as the values detected in African surface water (Table 1).

During the UV$_{254}$/H$_2$O$_2$ process it was observed a slight increase of revertants followed by
disappearance of revertants at the highest UV$_{254}$ exposure.

Investigations of the genotoxic endpoints demonstrated that the untreated solutions could not
be classified as genotoxic since the induction ratio was below the threshold value of 1.5
(Tables 7-8). On the contrary, a statistically significant increase in umuC induction was
recorded for ZDV undiluted solutions for UV$_{254}$ doses corresponding to ZDV conversions of
45% and 90% for both UV$_{254}$ and UV$_{254}$/H$_2$O$_2$ processes (Table 7). The genotoxic activity
showed a decreasing trend as the dilution factor of the solutions increased.

STV genotoxic data demonstrated (Table 8) that only the treated solutions were able to
induce a significant SOS response with IF higher than 2 also observed for the highest dilution
factor (1:1000), which corresponds to an initial concentration of STV of 4.3 µg·L⁻¹. The results collectively may indicate that some photoproducts generated during the photolytic processes could have genotoxic activity. However, genotoxic activity was not observed in the solutions treated for prolonged treatment times, thus suggesting that the genotoxic transformation products observed in earlier times might have further evolved to non-genotoxic metabolites.

4. Conclusions

The removal of stavudine and zidovudine by UV₂₅₄ radiation without and with hydrogen peroxide was investigated in a microcapillary film photoreactor using minimal quantities of water samples. Higher UV₂₅₄-photolysis quantum yields were observed for zidovudine, \((2.357 \pm 0.0589) \cdot 10^{-2}\) mol·ein⁻¹ in the pH range from 4.0 to 8.0, while stavudine quantum yield was 28-fold lower \((8.34 \pm 0.334) \cdot 10^{-4}\) mol·ein⁻¹ in the pH range from 6.0 to 8.0. The second-order rate constant of reaction with hydroxyl radicals was \((9.98 \pm 0.68) \cdot 10^8\) M⁻¹·s⁻¹ (pH range 4.0 – 8.0) for zidovudine and \((2.03 \pm 0.18) \cdot 10^9\) M⁻¹·s⁻¹ (pH: 6.0 – 8.0) for stavudine. The well known ecotoxicological tests using A. fischeri and D. magna as bioindicators did not evidenced acute or chronic effects. A hormetic effect was observed for the first time in R. subcapitata for ZDV and STV treated solutions at different UV₂₅₄ doses after a dilution from 1:10 to 1:100.

On the contrary, specific tests using Salmonella t. revealed mutagenic and genotoxic activity of the ZDV and STV samples also at high dilution factors depending on the type of the photolytic treatment and substrate conversion.

Generally, UV₂₅₄ photolysis in the presence of hydrogen peroxide reduces the ecotoxicological risk associated to direct photolysis of the aqueous solutions containing the antiretrovirals, but for this purpose UV₂₅₄ doses (≥ 2000 mJ·cm⁻²), significantly higher than...
the levels suggested for the water UV disinfection processes (50 – 200 mJ·cm\(^{-2}\)) are necessary. This study pointed out the critical importance of selecting suitable bioindicators depending on chemical and biological properties of the selected xenobiotics detected in STP effluents and in surface waters.
