Abstract
We report the synthesis of five new azulene containing dyes, having D-π-A type structures. These dyes are synthesised using a sulfonium salt cross-coupling reaction. The dyes have been evaluated spectroscopically, electrochemically, crystallographically, and as sensitizers in dye-sensitized solar cells. We propose a rationale for the dyes’ spectroscopic properties and performance in cells, based on conformational data derived from their crystal structures.

1. Introduction

Since the earliest reports on dye-sensitized solar cells (DSSCs) over 25 years ago,1,2 much effort has been expended in the optimisation of these devices, in pursuit of higher photoelectric conversion efficiencies (PCEs, η). Central to this effort has been the design, synthesis and evaluation of dyes with enhanced properties in terms of photon capture, electron injection, dye adhesion and device lifetimes, etc.3,4 Dyes consisting of ruthenium polypyridyl complexes such as N7195 achieved notably high PCEs, but the high cost of ruthenium is an impediment to the commercialisation of cells based on such dyes. In contrast, DSSCs that use wholly organic dye molecules can avoid the use of expensive metals. Design principles for high efficiency organic dyes have been established, with the donor–π linker–acceptor–anchor (D-π-A) assembly proving to be highly successful.6,7 Of the various known electron donor motifs, alylamines have proven especially effective.8–10 Regarding the π linker motif, a wide variety have been explored, mostly heterocycles, amongst which thiophenes, oligothiophenes and annulated thiophenes have all proven often to influence positively the overall cell efficiency.11–16 An anchoring group is required to immobilise the dye molecule on the metal oxide surface; a variety of different anchor groups have been investigated, including phosphonic acids and carboxylic acids and their derivatives (esters, acid chlorides, carboxylate salts or amides).17,18 Carboxylic acid and cyanoacrylic acid groups are most frequently used for DSSC dyes. More specifically, because of its excellent electron withdrawing characteristics, cyanoacrylic acid is used in most D-π-A organic dyes, where it fulfils the dual role of acceptor and anchor. In contrast, simple carboxylic acid anchors are usually used for transition metal complexes where metal-to-ligand-charge-transfer (MLCT) predominates.

The aims of the present study were to synthesise organic dyes for DSSCs that comprise an azulene ring as the donor motif, to characterise these dyes using a variety of techniques, and to evaluate their performance in solar cells. Azulene (1) is a bicyclic, nonbenzenoid aromatic hydrocarbon and is an isomer of

Azulenes have been of interest to chemists due to their striking colours, interesting chemistry and unusual electronic properties. Azulene derivatives may be used as advanced materials for optoelectronic devices, charge-transport, nonlinear optics and chemical sensing; some recent reviews serve to summarise these areas.\textsuperscript{32,33} Some azulene derivatives have also been shown to have anti-inflammation,\textsuperscript{34,35} anti-ulcer,\textsuperscript{36–38} anticancer\textsuperscript{39–42} and anti-HIV\textsuperscript{43} properties. Azulene is a non-alternant hydrocarbon, unlike naphthalene, which leads to HOMO nodes at C2 and C6 and LUMO (S1) nodes at C1 and C3 (Fig. 1), causing relatively small repulsion between the electrons occupying these orbitals, meaning a low S0 transition energy in the UV. Therefore naphthalene is colourless but azulene 1, because the S0 – S1 transition corresponds to the green and red regions of the spectrum, is a deep blue colour. The absorption spectra for substituted azulenes are very sensitive to the electronic nature of the ring substituents.\textsuperscript{45} Hence, by careful design of the substituents, the entire visible (and IR) spectrum is accessible. This ability to tune the chromophore’s absorption spectrum makes azulene an attractive motif for exploitation in DSCs.

In the context of solar cells, sporadic reports of azulene derivatives have appeared in various contexts. Emrick and co-workers employed copolymers of 2-substituted azulene with zwitterionic electrolytrates in bulk-heterojunction (BHJ) solar cells.\textsuperscript{46} Imahori and co-workers evaluated copolymers of 1,3-disubstituted azulene and diketopyrrolopyrroles or benzothiazolodiazoles\textsuperscript{47} in BHJ solar cells, shortly after which and Liu, Zhang and co-workers reported two similar azulene copolymers, as well as a further example possessing distinct connectivity (a 4,7-disubstituted azulene).\textsuperscript{48} Most recently, Gao and co-workers reported a copolymer incorporating a 6,6′-disubstituted 2,2′-biazulenyl.\textsuperscript{49} Aside from polymer BHJ solar cells, Huang and co-workers recently reported the use of an azulenesquaraine small molecule in an organic photovoltaic (OPV) device.\textsuperscript{50} Torres, Guldi and co-workers reported a OPV device comprising azulenocyanines immobilised on carbon nanotubes.\textsuperscript{51} In the area of perovskite solar cells, an azulene-containing hole-transport material has been shown by Wakamiya, Saeki, Scott, Murata and co-workers to exhibit performance superior to that of Spiro-OMeTAD, the most commonly used hole-transport material.\textsuperscript{52} There have been reports of electron injection from an azulene into the conduction band of titania, from Piotrowiak, Galoppini and co-workers\textsuperscript{33,54} (either employing azulene itself, sequestered in a hemiacetale, or using azulenes bearing methyl ester anchoring groups), but in no instance was construction of a DSSC attempted.

To our knowledge, the peer-reviewed literature contains only two reports of azulene containing dyes being used in DSSCs. In 2007, Cheng, Wang, Zhang and co-workers reported the synthesis of dyes 3–6 (Fig. 2), comprising either an azulene attached directly to a cyanoacrylic acid (3, 5), or with a vinylene linker between the azulene and the anchor motif (4, 6).\textsuperscript{55} They found the presence of the vinylene linker led to a bathochromic shift of $\lambda_{\text{max}}$ and an increase in $\eta$ with respect to the dyes lacking this motif, due to increases in both $J_{SC}$ and $V_{OC}$. Additionally, they observed an increase in $\eta$ for alkylated azulenes 5 and 6 compared to their respective non-alkylated counterparts 3 and 4. The authors ascribe this latter effect to the alkyl groups disfavouring dye aggregation on the titania surface. In 2014, Hanaya and co-workers reported the evaluation of phenylazulene 7 (Fig. 2) as a dye in a DSSC.\textsuperscript{56} The focus of this study was the evaluation of an alternative redox mediator, Br/Br3, in place of the more commonly used I/I3 system, with the authors finding that the Br/Br3 system afforded a greater $V_{OC}$ and hence $\eta$. The patent literature also contains azulene dyes for DSSCs. Two patents filed by TDK\textsuperscript{57,58} describe azulenes 8–17 (Fig. 2). The emphasis of the patent is on the fact that these dyes are all more resistant to photobleaching than a comparator ruthenium-based dye: no further data are given. A patent from SOLVAY\textsuperscript{59} reports azulenocyanines of type 18 (Fig. 2), which differ from those reported previously by Torres, Guldi and co-workers\textsuperscript{51} in that the azulenocyanines bear anchoring groups for the specific purpose of attachment to titania and use in a DSSC. (Azulenes are also described elsewhere in the patent literature in the broader context of photovoltaics.\textsuperscript{50,60}) Finally it should be noted that prospective azulene-based dyes for DSSCs have been considered theoretically.\textsuperscript{52}

2. Results and discussion

In the present study, we undertook two rounds of dye design, synthesis and characterisation. In the first instance we targeted dyes of the D–π–A design, with a 1-substituted azulene as the donor motif (as per the majority of examples in Fig. 2), and a cyanoacrylic acid as the acceptor and anchor motif. For the π-linker, we opted to employ a thiophene ring, whose ability to induce bathochromic shifts of absorption maxima and to afford increased extinction coefficients has been documented.\textsuperscript{11–16} Specifically we targeted azulene-thiophene-cyanoacrylic acid (“Az-tcaa”) 19 and 4,6,8-trimethylazulene-thiophene-cyanoacrylic acid (“TMAz-tcaa”) 20 (Fig. 3). The rationale for targeting 20 was that the methyl substituents may disfavour dye aggregation on the titania surface, analogous with the reason proposed previously\textsuperscript{25} for the increased performance of 6 with respect to 4. Retrosynthetically, it was envisaged that the targets could be accessed by a Knoevenagel condensation of aldehyde 22 and cyanoacetic acid. Aldehyde 22 would be accessed in turn using cross-coupling methodology, from an appropriately functionalised azulene 23 and a thiophene–2-carbaldehyde metalated at the 5-position, 24. The C1 and C3 positions of azulene are the most nucleophilic, so a haloazulene of type 23 would be expected to be accessible from the parent azulene 1 or 25 through an S$_2$Ar halogenation.

Of the various cross-coupling methodologies that could be used to synthesise 22, we opted to employ a Suzuki–Miyaura reaction, since there is precedent for such couplings using 1-haloazulenes as the substrate,\textsuperscript{51} in conjunction with bulky monodentate phosphate
ligands. The required nucleophilic reaction partner of type 24 was therefore (5-formylthiophen-2-yl)boronic acid (29). This was synthesised through a variant of reported procedures, as shown in Scheme 1a. We found that 29 could be conveniently purified by recrystallization from water, although the polymorph so formed was shown by x-ray crystallography to be a monohydrate (see ESI). This water of crystallisation could subsequently be removed simply by drying the ethereal solution of 29/C15H2O over MgSO4.

An azulene cross-coupling partner was prepared by direct halogenation of azulene (1) with N-chlorosuccinimide to give 1-chloroazulene (30). Clean monohalogenation of azulene through an S_NAr process is not possible, since the resultant 1-haloazulene can readily undergo a second substitution. Thus, even with only 1 equivalent of NCS, formation of a small quantity of 1,3-dichloroazulene (31) is unavoidable (Scheme 1b). Haloazulenes are also rather unstable, but 30 is sufficiently stable to be separable from 31 by chromatography. With both coupling partners in hand, we attempted their union using reaction conditions described by Buchwald. In the first instance (Scheme 1c), however, thiényl azulene 32 was produced in only 6% yield. We ascribe this low yield primarily to instability of boronic acid 29 to the reaction conditions, as we observed significant quantities of protodeborylation product (thiophene-2-carbaldehyde) being formed. Decomposition of 30 may also have contributed to the low yield. Use of the bromo analogue of 30 was considered but not attempted, since although it would be more reactive, it is appreciably more unstable. Attempts at reaction optimisation (variation of solvent, reaction stoichiometry, etc.) afforded only marginal improvements in yield.

A significant improvement in the cross-coupling yield was achieved by varying the nucleophilic coupling partner, employing a pinacolborane group in place of the boronic acid, and with the aldehyde protected as an acetal. Thus, coupling of 30 with dioxa-borolane 33 gave protected thiénylazulene 34 (which was not purified); immediate deprotection by transketalisation in acetone.

---

Fig. 2. Previously reported azulene-containing dyes used in DSSCs.
gave desired aldehyde 32 in a much-improved 54% yield over 2 steps (Scheme 2a). The analogous reaction sequence with 4,6,8-trimethylazulenyl halide 35 gave the corresponding aldehyde 37 in 59% yield (Scheme 2b). Finally, the yields were improved still further by the use of azulenesulfonium salts 38 as pseudohalides in the cross-coupling (Scheme 2c), methodology recently developed by us to address the issue of the instability of azulenyl halides.68

With the required aldehydes 32 and 37 in hand, we carried out the Knoevenagel condensation to furnish the desired dyes 19 and 20 respectively, as shown in Scheme 3. Literature dye 3 was also synthesised55,69 for spectroscopic comparison with 19.

Absorption spectra for 3, 19 and 20 were acquired in acetonitrile (see ESI), and key spectroscopic data are shown in Table 1. The spectra have similar features, such as an absorption in the 400–500 nm region, a region where corresponding the unsubstituted parent azulene compounds do not absorb. When comparing literature dye 3 with our dye 19 incorporating a thiophene π-linker, a bathochromic shift of $\lambda_{\text{max}}$ of 50 nm is evident.

Cyclic voltammetry (CV) was then used to determine the oxidation potentials of the three azulene based dyes: Az-1-caa (3), Az-1-tcaa (19), and TMAz-1-tcaa (20) (Figs. 4–6). All CVs were run in dry THF with 0.1 M tetrabutylammonium hexafluorophosphate (Bu4NPF6) supporting electrolyte at a scan rate of 100 mV s$^{-1}$ (see ESI for full details). Three scans were taken for each run. The voltammograms show plots for the first and third scans only. All the dyes exhibited at least one oxidation peak; however the oxidations were all irreversible so it was not possible to calculate the $E_{1/2}$ potentials. The peak oxidation potentials vs. Fc/Fc$^+$ are summarised below (Table 2). The position of the HOMO is estimated from the
onset of the oxidation wave in the irreversible scans.

The dye with three methyl groups on the azulene (20) has a similar oxidation potential to the unsubstituted analogue (19). Furthermore, the literature dye without a thiophene linker (3) has a significantly elevated oxidation potential compared with the dyes with a thiophene linking unit (19 and 20). This suggests that the thiophene linker makes it easier to extract an electron from the dye molecule and that the resulting cation should be more stable. Also of note, 20 exhibited two oxidation waves, neither being reversible (Fig. 6). This means that two electrons can be removed from this molecule, resulting in a dication. Crucially, all of the voltammograms show that breakdown products are generated following oxidation of the dyes. This can be seen by comparing the traces of scan 1 (black line) and scan 3 (red line) in each voltammogram. With scan 1, there is no sign of any oxidation before the main oxidation peak begins, e.g. at approx. 0.3 V in Fig. 6. On subsequent scans, there is evidence of oxidation processes occurring at potentials lower than the main oxidation peak, e.g. in Fig. 6 two minor oxidation peaks can be seen at ~0.049 V and 0.263 V vs Fc/Fc⁺.

These minor oxidation waves appear to be at least partially reversible since they have corresponding reduction waves. Since the minor oxidation waves did not occur in the first scan, they must be due to species generated from the oxidised dye, which is a radical cation. Such a radical cation would be highly reactive and may react with other molecules present e.g. solvent, other dye molecules (hydrogen abstraction) or other radicals (combination).

The cyclic voltammetry data discussed above suggest these dyes may have a limited lifetime in a DSSC. We were mindful of the fact that they are known to exhibit reversible electrochemistry. Therefore, the objective of the second phase of this work was to synthesise dyes which exhibited reversible electrochemistry, which through modifications to Az-1-tcaa (19) and TMAz-1-tcaa (20) were rationally designed to stabilise their oxidised states.

A literature search for azulene-containing compounds with reported electrochemical data, and that exhibit reversible oxidation waves, has suggested that both the azulene C-1 and C-3 positions must be substituted, preferably with substituents with steric bulk e.g. tert-butyl groups. Gerson et al. have reported that only azulenyl radical cations substituted at both the C-1 and C-3 positions were sufficiently persistent to be characterised by EPR spectroscopy, and tert-butyl groups were necessary to enable ENDOR and TRIPLE resonance studies. The radical cations of 1,3-di-tert-butylazulenes 40 (Fig. 7) persisted for 20–40 min at 273–283 K. The authors offered no explanation as to why the tert-butyl groups should confer stability to the azulene radical cation. 1,3-Dimethylazulene radical cations were more stable than those of unsubstituted azulene, but were not so long-lived as the 1,3-di-tert-butylazulene ones. It is postulated that the tert-butyl groups shield the radical unpaired electron purely through their steric bulk, preventing the close approach of species that would otherwise be liable to react with the radical. Shoji, Ito, Morita and co-workers have reported that 1,3-bis(methylthio)azulene 41 also exhibit reversible electrochemistry. The methylthio groups may also stabilise the corresponding radical cations through steric shielding; conjunction with the sulfur atoms may also be important.

We resynthesized 1,3-di-tert-butyrlazulene and 1,3-bis(methylthio)azulene and verified that they both do exhibit reversible electrochemistry (ESI, Figs. S4–S5). An azulenyl nitrone reported by Becker, Ecchegoyen and co-workers to exhibit reversible electrochemistry was also resynthesized. While this did not display evidence of decomposition products, nor did it display fully reversible electrochemistry in our hands, as the amplitude of the oxidation wave decreased in the second and subsequent scans (ESI, Figs. S6–S7). These literature examples of azulenes that exhibit reversible electrochemistry inspired a second generation of dye designs, incorporating both the azulene-thiophene-cyanoacrylic acid D-π-A motif in dyes 19 and 20, and also the C3 substituents of 40 and 41. It was hoped that such dyes would display fully reversible electrochemistry, whilst at the same time retaining the D-π-A motif and hence favouring electron injection from the excited state. The second generation target dyes 42–44 are shown in Fig. 8.

Of the dye targets 42–44, we first sought to synthesise 42, bearing a tert-butyl group. 1,3-Di-tert-butyrlazulene (40, R = R2 = H) can be synthesised directly from azulene by means of a double Friedel–Crafts alkylation, using excess tert-butanol and HBF4. However, attempts to use this procedure to introduce a tert-butyl group directly onto the C3 position of aldehyde 32 were unsuccessful, most likely because the functionality present in this

![Fig. 6. Voltammogram for TMAz-1-tcaa (20), 0.5 mM in THF. Supporting electrolyte 0.1 M Bu4NPF6. Scan rate 100 mV s⁻¹.](image)

![Fig. 7. Reported classes of azulenes exhibiting reversible electrochemistry.](image)

![Fig. 8. Second generation azulene D-π-A dye targets.](image)
precursor to dye 19 was incompatible with the harsh Friedel–Crafts reaction conditions. Instead, therefore, we opted to synthesise 42 via a reaction sequence analogous to that for 19, but starting with 1-tert-butylationulene 45 (i.e. a synthesis with the tert-butyl group present from the beginning). However, accessing pure 1-tert-butylationulene (45) is not straightforward. Treatment of azulene with only one equivalent of tert-butanol and HBF₄ unavoidably leads to over-substitution, i.e. formation of some 1,3-di-tert-butylationulene (40, R = R₂ = H) in addition to the desired 1-tert-butylationulene (45); in our hands these two products proved to be difficult to separate by chromatography. To overcome this problem, we devised a new synthesis of 1-tert-butylationulene. It is known that 1,3-di-tert-butylationulene (40, R = R₂ = H) undergoes ipso substitution upon exposure to Vilsmeier conditions, giving 1-formyl-3-tert-butylationulene. Furthermore, there are reported examples of 1-formylazulenes undergoing dehydroxylation upon treatment with pyrrole. Exploiting these literature reports, we were able to synthesise pure 1-tert-butylationulene (45) as shown in Scheme 4. Double Friedel–Crafts alkylation of azulene gives 1,3-di-tert-butylationulene, which then undergoes substitution of a tert-butyl group for a formyl group to give 46, as per the literature procedures. Application of the pyrrole-mediated azulene dehydroxylation protocol to 46 has not been reported previously, but in the event proceeded smoothly to give the desired 45.

With a reliable route to 45 established, we utilised our sulfoxide salt cross-coupling methodology to elaborate this towards dye target 42. Treatment of 45 with tetramethylenesulfoxide 47 and trifluoroacetic anhydride led to azulenesulfoxonium salt 48 (after anion exchange). This in turn underwent Suzuki–Miyaura cross-coupling followed by acetal deprotection to give aldehyde 50 (the tert-butyl analogue of 32), as per our reported procedure (Scheme 5).

To synthesise methylthio-substituted dyes 43–44, we were able to employ a more convergent route, introducing the desired –SMe substituent directly onto the azulene 3-position of thienyl aldehydes 32 and 37, that we had prepared previously. According to the procedure of Shoji, Morita and co-workers, exposure of an azulene to a sulfoxide and an activating agent leads to formation of an azulenesulfoxonium salt. In many instances, trifluoroacetic anhydride (TFAA) will suffice as the activating agent, but for more electron-poor azulenes (or unactivated arenes), tri- fluoromethanesulfonic anhydride (Tf₂O) is used. Thus, as shown in Scheme 6, the most nucleophilic position in azulenes 32 and 37 is still the azulene C3 position, regardless of the presence of the thiophene, and it is this position that reacts with the activated sulfoxide to give azulenesulfoxonium salts 51–52. Whereas we have exploited azulenesulfoxonium salts for cross coupling (c.f. Schemes 2 and 5), Shoji, Morita and co-workers have demonstrated that they may be readily dealkylated to give the corresponding thioethers. In our case, 51 and 52 were not purified, but were instead directly subjected to demethylation conditions to furnish the desired aldehydes 53 and 54.

With aldehydes 50, 53 and 54 in hand, access to target dyes 42–44 required only the final Knoevenagel condensation with cyanoacrylic acid. Application of the Knoevenagel conditions employed for the first-generation dyes (catalytic piperidine, reflux in acetonitrile) did lead to formation of the target dyes, but the presence of appreciable amounts of residual starting material and other products hampered their purification. The first generation dyes were purified in a straightforward fashion by trituration with dichloromethane, followed by recrystallization, but this protocol was not applicable to the second generation dyes — their greater solubility in dichloromethane precluded effective trituration, and direct recrystallization of the crude was not successful. We therefore sought to improve the Knoevenagel condensation to drive the reaction to completion and reduce the proportion of impurities present in the crude that were interfering with recrystallization. Aside from piperidine, many other promoters of the Knoevenagel reaction have been reported in the literature. Of various literature procedures we tried, use of a stoichiometric quantity of 6-aminoacaproic acid in place of piperidine was most beneficial.

Thus, after optimisation, we found that treatment of 50 with 1 equivalent of 6-aminoacaproic acid and 1.5 equivalents of cyanoacrylic acid, in ethanol at 50 °C, led to consumption of starting material by TLC after 3.5 h. Addition of 1 M H₂SO₄(aq) then gave a tar, which was dissolved in dichloromethane and washed with water; removal of solvent was followed by a successful recrystallization to give target dye 42 in 49% yield. The same procedure, when applied to 53 and 54 gave a precipitate upon addition of acid, which could simply be isolated by filtration and recrystallized to provide 43 (67% yield) and 44 (63% yield) respectively, as shown in Scheme 7.

With the target second-generation dyes 42–44 in hand, these were characterised by the same techniques employed for 3, 19 and 20. UV–Vis spectra were acquired at 0.01, 0.03 and 0.05 mM concentrations. During the dye synthesis and purification steps, it had been noted that the colour of the dyes in solution differed slightly depending on the solvent used (solvatochromism). When in dichloromethane solution, for instance, the dyes appeared to be somewhat bluer than when acetonitrile was used. Spectra were therefore acquired in three solvents: acetonitrile (MeCN), tetrahydrofuran (THF) and dichloromethane (DCM) (see ESL Figs. S8–S19). The UV–Vis data for the 2nd generation dyes are presented in Table 3.

The three 2nd generation dyes all have two principal absorption bands in the region of interest, one in the visible region with λmax ≈ 430–520 nm (band A) and the other in the near UV with λmax ≈ 350–380 nm (band B). Dye MeTTMAz-1-tcaa (44) has an additional absorption band with λmax ≈ 320 nm. The band A absorption is assumed to be due to charge transfer between the thiophene linker and the azulene moiety. With dyes tBuAz-1-tcaa (42) and MeTAz-1-tcaa (43) (i.e. those with an unsubstituted azulene 7-membered ring), the absorption band A is the more intense of the two. However, with dye MeTTMAz-1-tcaa (44), the situation is reversed, with the absorption band A being less intense than the absorption band B. Indeed, absorption band A for MeTTMAz-1-tcaa (44) is only around half the intensity of absorption band A for MeFAz-1-tcaa (43). This is an unexpected result at first glance, since the only difference between these two dyes is the presence of the

![Scheme 4. New synthesis of 1-tert-butylationulene.](image-url)
additional methyl groups in 44, which do not extend the chromophore. Upon reinspection of the UV–vis data for the first generation dyes, the same effect can be discerned. The visible-region absorption band for TMAz-1-tcaa (20) is significantly less intense than for Az-1-tcaa (19). Once again, the only difference in structure is the presence of the additional methyl groups in 20.

A possible explanation for the phenomena described above may be found in x-ray crystallographic data acquired for the dyes. Crystals suitable for x-ray diffraction were grown for dyes 20, 42, and 43. The structures are depicted in Figs. 9–11.

In the case of MeTAz-1-tcaa (43), the structure is essentially planar (Fig. 11), with a torsion angle between the azulene and thiophene rings (defined as Az(C2)-Az(C1)-Thio(C2)-Thio(C3)) of \( \theta = 0.9 \) (3). As such, it seems optimal orbital overlap is achievable in the solid state (and presumably also in solution) and the two rings are fully conjugated. In the case of tBuAz-1-tcaa (42), the solid-state structure exhibits some distortion away from planarity (Fig. 10), with the analogous torsion angle being \( \theta = 26.8 \) (3). However, most strikingly of all, in the case of TMAz-1-tcaa (20) the

**Scheme 5.** Synthesis of aldehyde 50, precursor to dye 42.

**Scheme 6.** Direct late-stage C3-functionalisation of thiienyl aldehydes.

**Scheme 7.** Final Knoevenagel condensations to produce second generation dyes.
structure is far from planar (Fig. 9), with the analogous torsion angle being $\theta = 122.2(3)^\circ$, i.e. the azulene and thiophene rings are closer to being perpendicular than they are to being coplanar. Rather than this being due to any crystal packing effects, we propose this is an unavoidable consequence of the presence of the methyl groups on the azulene 7-membered ring. Thus, if the azulene and thiophene rings were coplanar, the azulene 8-position methyl substituent would be significantly occluded with the thiophene C3 hydrogen. Relief of steric strain therefore necessitates that the thiophene ring rotates out of planarity with the azulene, which will impair the conjugation of the two rings. Since the visible region absorption band is proposed to arise from charge transfer between the azulene and thiophene rings for these dyes, the reduced $\pi$-orbital overlap between these two motifs may therefore explain the relatively lower extinction coefficient observed for TMAz-1-tcaa (20) in comparison with the analogue Az-1-tcaa (19) which lacks the methyl groups. In the case of MeTTMAz-1-tcaa (44), although we were not able to obtain an x-ray crystal structure, we can nevertheless propose that the same effect is in operation, leading to the less intense absorption in the visible region.

Fig. 9. (A) ORTEP structure of TMAz-1-tcaa (20) and (B) rotated through 90° in the horizontal plane to show the “end elevation” view. Ellipsoids are represented at 50% probability. H atoms are shown as spheres of arbitrary radius. CCDC #1815403.

Fig. 10. (A) ORTEP structure of tBuAz-1-tcaa (42) and (B) rotated through 90° in the horizontal plane to show the “end elevation” view. Ellipsoids are represented at 50% probability. H atoms are shown as spheres of arbitrary radius. CCDC #1815402.

Fig. 11. (A) ORTEP structure of MeTAz-1-tcaa (43) and (B) rotated through 90° in the horizontal plane to show the “end elevation” view. Ellipsoids are represented at 50% probability. H atoms are shown as spheres of arbitrary radius. CCDC #1815401.
with respect to MeTAz-1-tcaa (43) that lacks the methyl groups (and which can be seen in Fig. 11 to be fully planar).

Cyclic voltammograms (CVs) were acquired for the three 2nd generation dyes 42-44. All three dyes show quasi-reversible redox chemistry (Figs. 12–14). The radical cations produced by dye molecule oxidation clearly survive to be reduced back to the dye molecules as evidenced by the reduction waves in the reverse sweep which correspond to the oxidation waves in the forward sweep of the CVs. There is no sign of any decomposition products evident in the second and subsequent scans. For all three dyes, the second and subsequent CV scans are almost exactly super-imposed (scan 1 and scan 3 are plotted for each dye), which indicates that there is little or no depletion of the dye species in the vicinity of the working electrode. This is in contrast with the first generation dye analogues (Figs. 4–6), where the magnitude of the oxidation waves diminish with each successive scan indicating that the dyes are being consumed.

Both of the radical shielding groups therefore appear to do a good job of protecting the radical cation formed by abstracting an electron from the dye molecules. The CVs of the dyes containing a methylthio group (MeTAz-1-tcaa 43 and MeTTMAz-1-tcaa 44) are very similar; the three methyl groups attached to the 7-membered ring increase the dye oxidation potential by approximately 30 mV. The difference between the methylthio and tert-butyl shielding groups is more striking; the shift in oxidation potential between MeTAz-1-tcaa (43) and tBuAz-1-tcaa (42) is over 250 mV, showing that the dye HOMO energy level can be ‘tuned’ to a certain extent by changing the shielding group. Electrochemical data extracted from the cyclic voltammograms are presented in Table 4. In the ideal case of a reversible one electron redox couple, the difference between the peak cathodic and anodic potentials (Epc and Epa), \( \Delta E_p \) is approximately 59 mV (at 25 °C) and the ratio of the peak anodic and cathodic currents (Ipa and Ipc) is unity. The three dyes depart slightly from this ideal; \( \Delta E_p = 131 \text{ mV} \) for all three dyes and Ipc/Ipa varies from 0.92 to 0.94. It is interesting to note that the values for \( \Delta E_p \) are identical for each dye, suggesting that the slower than ideal electrode dynamics may be due to a different factor, e.g. solvent or electrolyte, which were constant for each experiment.

Energy level data for the first and second generation dyes are summarised in Table 5. The ground state (D0/D+) potentials and band gap (Eg) values are taken from the electrochemistry and UV/Vis spectrometry results (see above). Subtracting Eg from D0/D+ gives the ground state HOMO level. All of the dyes satisfy the energy level requirements to function as DSSC sensitizers. The redox potential of the ground state is 0.44–0.70 V below that of the I-/I3 couple used in the electrolyte.

Construction and evaluation of DSSCs using the first and second generation dyes was then undertaken. The iodide/triiodide redox couple was used, with a 1 cm² cell area. Initial experiments with 44 indicated that addition of lithium iodide and chenodeoxycholic acid (CA) to the electrolyte were both beneficial. Thus, for comparison of all the dyes, the electrolyte composition shown in Table 6 was used. Cells constructed concurrently using dye N719 were also evaluated as a reference for comparison.

The DSSC evaluation results are presented in Table 7 (and graphically in Figs. S20–S23, see ESI). The best result was achieved with the reference dye N719; of our dyes, the highest mean efficiency of 1.20% was achieved with the first generation dye TMAz-1-tcaa (20). The next highest performing cells were based on the second generation dye MeTTMAz-1-tcaa (44). It is interesting to note that, contrary to expectation, the best performing dyes were...

the ones based on 4,6,8-trimethylazulene (25) and therefore had a methyl group in the seven-membered ring that causes a large torsional angle between the plane of the azulene rings and the thiophene ring of the linker group (see above). This was expected to disrupt conjugation between the azulene and thiophene rings and therefore restrict charge transfer between them too, limiting DSSC performance. However, another factor that detrimentally influences DSSC efficiency is re-combination of electrons injected into the TiO₂ with the oxidised dye species. The high torsional angle of the dyes based on 4,6,8-trimethylazulene may conceivably be beneficial in this respect, helping to block charge transfer from TiO₂ to the oxidised azulene moiety, resulting in improved efficiency.

Two dyes were selected for a more detailed electrolyte additive analysis: first generation dye TMAz-1-tcaa (20) and second generation dye tBuAz-1-tcaa (42). The three additives to be evaluated in combination were lithium iodide (Li), chenodeoxycholic acid (CA), and guanidine thiocyanate (GT). GT has been shown to increase DSSC short circuit current density (JSC) and therefore increase cell efficiency.³⁷ The DSSC evaluation results for these modified electrolytes are presented in Table 8 (and graphically in Figs. S24–S27, see ESI). The best DSSC efficiencies for both dyes were obtained with the combination of both Li and CA. As before, the first generation dye TMAz-1-tcaa (20) produced the highest efficiency of 1.33% while the second generation dye tBuAz-1-tcaa (42) gave an efficiency of 0.92%. The addition of guanidine thiocyanate to the DSSC electrolyte actually had a detrimental effect, reducing DSSC efficiency by 25–33%. Rather than increase short circuit current density, the JSC was severely reduced while open circuit voltage was increased. The addition of Li and/or CA to the electrolyte both have a positive influence on cell efficiencies and seem to exhibit a synergistic effect when both are added together. The Li and CA acid both influence the DSSC electrolyte actually had a detrimental effect, reducing DSSC efficiency by 25–33%. Rather than increase short circuit current density, the JSC was severely reduced while open circuit voltage was increased.

3. Conclusions

In summary, we have prepared five new azulene-containing dyes and evaluated their performance as sensitizers of titania in dye-sensitized solar cells. The synthesis of these dyes showcases the utility of the azulenesulfonium salt cross-coupling reaction that we have developed, with the dyes being accessed in only 4–5 steps from the parent azulene starting materials. The first generation of dyes (Az-1-tcaa 19 and TMAz-1-tcaa 20) were shown by cyclic
voltammetry to display non-reversible electrochemistry. This in turn prompted a literature search for azulenes that are known to exhibit reversible electrochemistry. Based on the results of this search, second generation dyes wererationally designed to target the desired property of reversible electrochemistry. The second generation dyes (1BuAza-1-tca 42, MeTcA-1-tca 43 and MeTTMaza-1-tca 44) were synthesised and it was shown by cyclic voltammetry that they do indeed exhibit reversible electrochemistry. However, when both the first and second generation dyes were evaluated in dye-sensitized solar cells, no trend for increased efficiency of the second generation dyes over the first generation dyes was observed. This implies that stability of the oxidised form of the dye was not the dominant factor in determining overall cell efficiency; we instead propose a rationale for the observed efficiencies based on an increased torsional angle between the azulene and thiophene rings induced by the presence of the additional methyl substituents in dyes 20 and 44 (the two dyes with highest η).
