A cyclohexadiene ligand prepared by microbial arene 1,2-dihydroxylation undergoes spontaneous rearrangement upon complexation to tricarbonyliron(0). Subsequent iron removal affords a novel route to formal arene 2,3-dihydroxylation products enantiomeric to those obtainable by direct microbial arene oxidation.

Since the first report in 1968, 1 enzymatic dihydroxylation of aromatic substrates to afford enantiopure building blocks for synthesis has become established methodology. 2 In excess of 400 arene cis-diol products have been reported. The vast majority of these are produced by organisms expressing toluene dioxygenase (TDO), naphthalene dioxygenase (NDO) and biphenyl dioxygenase (BPDO) enzymes. These metabolise substituted arene substrates in a regio- and stereoselective fashion. A reliable predictive model has been reported for such transformations 3 and the sense of enantioinduction is conserved across organisms and substrates (Scheme 1a). In contrast, organisms expressing benzoate dioxygenase (BZDO) enzymes oxidise benzoic acids in a process that exhibits not only different regioselectivity, but also the opposite sense of enantioinduction. For example, R. eutrophus B9, 4 P. putida U103 5 and P. putida KTSY01 (pSYM01) 6 oxidise benzoic acid to benzoate 1,2-cis-dihydrodiol 4 (Scheme 1b). Diol 4 has proved to be a versatile chiron for synthesis, having seen several applications, 7 most notably in the synthesis of tetracycline antibiotics. 8

Dienes such as 2 and 4 may be derivatised as the corresponding tricarbonyliron(0) complexes 9 and we have recently shown that the methyl ester of 4 coordinates to iron with complete facial selectivity. 10 The sole isomer obtained is that in which the diol is endo (6, Scheme 2a), which is noteworthy since the diene presents Lewis basic functionality on both faces. Coordination to iron permits stereoselective ligand modification at the carbons adjacent to the diene, by means of cationic η⁵-dienyl intermediates. 11 In this context we sought to access a complex in which the diol was exo, by protecting the diol as an acetonide (Scheme 2b). We reasoned that additional steric bulk on the lower face would disfavour the precoordination of the iron to a Lewis basic diol oxygen lone pair, which has been proposed to rationalise the facial selectivity observed previously.

In the event, treatment of acetonide 7 with Fe₂(CO)₉ in THF gave 9, in which the acetonide was indeed exo, but an isomerisation had occurred such that the ester was now conjugated to the diene (Scheme 3). The structure of 9 was determined by X-ray crystallography (Figure 1). 12
demetallation with trimethylamine N-oxide to afford uncomplexed diene (2S,3R)-11 (Scheme 4). The enantipurity of (2S,3R)-11 was determined to be >95% e.e. by means of ester reduction and subsequent formation of Mosher’s ester derivatives.‡ Attempted removal of the acetonide in (2S,3R)-11 upon exposure to Brønsted acid proved unsuccessful due to facile dehydration/rearomatisation. However, in preliminary experiments, iodine in methanol has been observed by NMR to afford 12 from (2S,3R)-11, albeit with a degree of concomitant rearomatisation.

Direct microbial oxidation of methyl benzoate to afford a 2,3-diol and subsequent acetonide formation has been reported. However, in this instance, the opposite enantiomer, (2R,3S)-11 was obtained. Indeed, the enantiomer reported here, (2S,3R)-11, has not been described to date; this iron-mediated diene rearrangement represents a new route to an arene 2,3-cis diol derivative antipodal to that obtained by direct biooxidation. Thus far, the synthetic utility of arene 2,3-cis-diols has been constrained by the comparative difficulty in accessing the non-natural enantiomeric series. We anticipate that the transformation reported here will be of great synthetic utility, for example in allowing the synthesis of d-configured carbasugars (many L-carbasugars have great synthetic utility, for example in allowing the synthesis of D-configured carbasugars (many L-carbasugars have been anticipated that the transformation reported here will be of difficulty in accessing the non-natural enantiomeric series. We anticipates the mechanism of formation of 9, isotopic labelling studies were undertaken to ascertain the identity of the migrating group. Biooxidation of para-deuterobenzoic afforded 13, which then permitted the preparation of 15 (Scheme 5). Regioisomer 14 was not formed, confirming that 9 arises through migration of the acetonide and not the carboxymethyl group.

In view of the above, a mechanism may be proposed that invokes an intermediate cationic η⁷-cyclohexadienyl intermediate,‡ 17. This could plausibly arise from initial formation of the expected 1,2-isomer 8, subsequent coordination of an unspecified Lewis-acidic species to an acetonide oxygen and C–O bond scission. Attack of the tethered nucleophile (exo to iron and ω to the electron-withdrawing group, as is precedent‡) would then generate 9 (Scheme 5). In addition to 17, the regiosomeric η⁷ cation 19 may also be formed as a transient intermediate by means of C–O bond scission at the other acetonide oxygen. The two cations 17 and 19 differ appreciably in electronic structure as the ester is conjugated to the dienyl system only in 17. Crucially, 19 is achiral; recombination of the tethered nucleophile at either terminus of the η⁷ dienyl ligand in 19 will effect racemisation of 8.‡ That (2S,3R)-11 and, by inference, 9 are not in fact racemic is suggestive of the reaction being under kinetic control. Specifically, formation of 17 may be kinetically favoured over 19 due to relief of steric strain as the ester α-carbon rehybridises such that the ester is in the plane of the dienyl system. If formation of 17 from 16 is effectively irreversible (due to the aforementioned preference for nucleophile recombination α- to the ester) and k_1/>>k_2 (Scheme 6), the e.e. of 9 will not be eroded.

Variable temperature ¹³C [¹H] NMR spectra for the carbonyl region of complex 9 clearly show fluxional behaviour. This fluxionality may be ascribed to turnstile rotation of the iron carbonyl ligands. The variable temperature spectra of 9 were simulated in order to derive the activation parameters for the exchange process of E_a = 46.8 ± 1.7 kJ mol⁻¹, ΔH° = 44.4 ± 1.6 kJ mol⁻¹, ΔS° = -22.8 ± 5.2 J K⁻¹ mol⁻¹ and ΔG°''(298) = 51.2 ± 3.1 kJ mol⁻¹. Use of ¹³C [¹H] VT-NMR to probe fluxionality in tricarbonyliron(0) complexes is well established and thermodynamic parameters have been derived.
by this method for numerous tricarbonyliron(0)diene complexes.18,19 The calculated value of $\Delta G^\circ_{298}$ for 9 is comparable to that for the analogous tropone complex ($\Delta G^\circ_{298}$ = 53.1 ± 2.1 kJ mol$^{-1}$).18

In summary, we have defined a rearrangement route to arne 2,3-cis diol derivatives of non-natural configuration. The complex through which this rearrangement is realised exhibits hindered ligand rotation, for which thermodynamic data are presented. Our approach is complementary to other strategies reported previously for achieving this "enantionic switch". For example, substituted iodozenes can undergo 2,3-dihydroxylation followed by reductive iodine removal,20,22 but this can preclude the use of diol derivatives possessing reductively labile functionality. The conceptually distinct approach of enantiodivergent synthesis has also been employed,21,23 requiring that two different synthetic routes be established. In contrast, the approach we describe utilises only oxidative conditions and will permit access to both enantiomers of a given target by the same synthetic pathway. Investigations to elucidate further the mechanism of formation of 9 and to demonstrate the scope of this transformation are underway in our laboratory and will be reported in due course.

We thank Prosidion Limited, EPSRC and CIKTN for a CASE studentship (to MAK). We also thank Prof. Andrew G. Myers (Harvard) for a generous gift of R.eutrophus B9 cells.
