I. INTRODUCTION

Experiments in magnetic fields can provide considerable insight into the electronic structure of excitons. In recent papers, we have shown that this structure becomes modified as the kinetic energy of the excitons becomes larger. To account for this, we have proposed a model in which the exciton ground state is mixed with excited states. The origin of the mixing is due to the dispersion curves for the valence band not being of simple parabolic form. In particular, the model provides an accurate quantitative description of the extensive data for CdTe. It leads to the important conclusion that the magnetic behavior of excitons cannot be explained simply by adding together the properties of the individual constituent particles (as has often been done in the literature): in fact, for CdTe, the motion-induced contributions to the magnetism begin to dominate those of the constituent electrons and holes as the exciton kinetic energy becomes larger. The motivation behind the present work was to show that this motion-induced behavior is observed in a different semiconductor and that the model constructed for CdTe is applicable here also, thus providing strong evidence for the universality of the phenomena in zinc-blende semiconductors. ZnSe is a particularly suitable choice because (i) its band gap is much larger than that of CdTe (so that contributions to the magnetism from interband mixing are much smaller) (ii) the ZnSe exciton binding energy is much greater than that of CdTe (so that quantum confinement effects on the individual charge carriers are relatively less important), and (iii) the magnetic moments (g values) of the electrons and holes are of opposite sign to, and, therefore, completely different from, those in CdTe, so that conclusive evidence can be obtained that it is not the magnetic moments of the individual particles that matter, but that of the exciton as a whole.

The key to our approach is the confining of excitons in quantum wells whose width $L$ is much larger than the exciton radius and in which the lowest confinement energies of the exciton are less than its binding energy. Under such circumstances, the exciton can be described with the “adiabatic” or center of mass (c.m.) approximation, in which it is treated as a composite hydrogen-like particle in which the electron and hole orbit one another (the internal motion). In a wide quantum well of sufficient depth, the translational motion of the center of mass can be described by a wave vector $\mathbf{K}$, whose component normal to the plane of the well is quantized, to a first approximation, according to $K_z = N \pi / L$, where $N$ is a nonzero integer. If the sample quality is sufficiently high, the exciton recombination energies for states with different values of $N$ can be resolved in photoluminescence (PL) experiments and their behavior under magnetic fields can be investigated. In particular, the Zeeman splitting, which is a measure of the exciton magnetic moment, can be studied for different values of $K_z$ and therefore as a function of kinetic energy. The magnetic moment itself is sensitive to the electronic structure of the exciton.

The plan of the paper is as follows. Following a description of the experimental data (Sec. II), we summarize briefly (Sec. III) the mixing process that modifies the magnetic properties. The model is applied successfully to ZnSe and our overall conclusions presented (Sec. IV).
II. EXPERIMENTAL DETAILS

A. Sample growth

Samples of ZnSe/ZnSSe with nominal well thicknesses of 20, 28, and 40 nm were grown by molecular beam epitaxy in a twin-chamber system, on top of 180 nm GaAs buffer layers on (001) GaAs substrates. The ZnSSe layer thicknesses were 1 μm on the GaAs side and 0.5 μm on the top side. The samples were characterized as described in Ref. 11, the well thicknesses determined by high resolution x-ray diffraction being 20.7, 29.4, and 43.7 nm, respectively. The sulfur contents in the barriers were 5.2%, 5.0%, and 5.8%, respectively, leading to barrier/well band gap differences on the order of 23–28 meV.

The specimens are strained such that the heavy-hole (HH) states lie lower than those of the light holes (LHs). At 2 K, we find that the strain contribution to the energy difference between the HH and LH excitons is about 13 meV.

The well widths are more than five times the ZnSe exciton Bohr radius (~3.5 nm) and the confinement energies of the excitons are smaller than the exciton Rydberg (e.g., for the lowest exciton state, the confinement energies in the 20 nm well are on the order of an meV, compared with $R = 20$ meV). 12

B. Photoluminescence spectra

Photoluminescence spectra for magnetic fields up to 6 Tesla were excited at 2 K by using the 325 nm line from a He-Cd laser. The angle $\theta$ between the magnetic field and the growth axis could be altered continuously between zero and 90°. Examples of the spectra for the sample with a well width of 43.7 nm are shown in Fig. 1.

The PL spectrum in zero magnetic field shows a clearly resolved set of lines whose energies can be described to a good approximation by

$$E_N = E_0 + N^2\hbar^2/8M_{HH}L^2,$$

where $M_{HH}$ is the HH exciton translational mass for motion in the growth direction, as appropriate for a particle of mass $M_{HH}$ in wide quantum well of large depth. Figure 2 shows this dependence for all three specimens, the value of $M_{HH}$ being 1.26$m_e$, where $m_e$ is the mass of a free electron. This is identical to the value obtained for ZnSe layers in Ref. 13 (where the relation between the translational mass and the Luttinger parameters14 is discussed). In the present work, the values of $K_p = N\pi/L$ for most of the transitions are in the range $(1-6) \times 10^6$ cm$^{-1}$ and therefore significantly greater than the magnitude of the photon wave vector $k_{\text{photon}}$ $(=0.5 \times 10^6$ cm$^{-1}$) so that the relevant part of the polariton dispersion curve is close to that of a simple c.m. exciton. The data in Fig. 2 thus enable the values of $N$ to be assigned for each specimen. A full discussion of the fit to the line positions is given in Ref. 11.

When a magnetic field $B$ is applied along the growth direction ([001], taken to be the $z$ axis), the lines in the PL spectra split and become circularly polarized (Fig. 1). For excitons formed from electrons and heavy-holes, the optically active states $|m_f, m_e\rangle$ in this field configuration are

![FIG. 1. PL spectra at 2 K from the specimen with well width 43.7 nm: (a) in zero magnetic field; (b) in a field of 6 T applied along the growth direction (the solid and broken lines refer, respectively, to $\sigma_+ \text{ and } \sigma_-$ polarization of the emitted light); (c) in a field of 6 T applied perpendicular to the growth direction. $|3/2, -1/2\rangle$ and $|3/2, 1/2\rangle$, where $m_f$ and $m_e$ are, respectively, the magnetic quantum numbers for the valence band hole and the conduction band electron. The Zeeman splitting between these states can be characterized by a parameter $g_{\text{exc}}$, defined according to $E_{\sigma_+} - E_{\sigma_-} = g_{\text{exc}} \mu_B B$ where $\mu_B$ is the Bohr magneton.

For an exciton at rest, one would expect $g_{\text{exc}} = g_{H\text{H}} - g_e$, where $g_{H\text{H}}$ and $g_e$ are, respectively, the heavy-hole and elec-

electron g values for this field orientation. However, from Fig. 1(b), it is clear that, for fields along the growth direction, the Zeeman splittings, and hence the values of $g_{\text{exc}}$, increase with the value of $N$. This can be seen more clearly in the fan diagram of Fig. 3 (where field dependent contributions to the energies due to diamagnetic shifts are also apparent). The continuous lines are on the form

$$E = E_N + DB^2 \pm g_{\text{exc}} \mu B/2.$$  

The term $DB^2$ describes the diamagnetic shift in the exciton line. For a given specimen, $E_N$, $g_{\text{exc}}$, and $D$ are functions of $N$.

Similar fan diagrams were obtained for the other two specimens and the corresponding values of $g_{\text{exc}}$ are given in Table I. The diamagnetic shifts are too small to be measured accurately, but approximate values of the parameter $D$ are also given in Table I.

In Refs. 1 and 2, it was pointed out that, when the values of $g_{\text{exc}}$ for a series of quantum wells are considered, it is not the values of the quantum numbers $N$ that are important: rather, what matter are the values of the $z$ component of the transversal wave vector. When the values of $g_{\text{exc}}$ for the three samples are plotted (see Fig. 5 of Sec. III) on the same graph as functions of $K_z = (N\pi/L)$, they lie on a common curve, as was the case for a series of CdTe quantum wells. The explanation of this is given in Sec. III. In consequence, we write

$$g_{\text{exc}} = [g_{\text{III}} + g(K_z)] \cos \theta - g_e,$$  

where $g(K_z)$ is a function of $K_z$ and where the field is at an angle $\theta$ to the growth direction. The $\cos \theta$ factor arises because the heavy-hole $g$ value makes a contribution $g_{\text{III}} \cos \theta$ to $g_{\text{exc}}$, while it is shown in Ref. 2 (see also Sec. III below) that the contribution from the $K_z$-dependent term has a $\cos \theta$ form. In contrast, the electron contribution is almost isotropic.

Figure 4 shows the dependence of $g_{\text{exc}}$ on $\theta$ for some of the exciton transitions in the sample with $L=43.7$ nm, and confirms the expected behavior. In particular, when the magnetic field is perpendicular to the growth direction, the energy splittings are now only slightly dependent on the values of $N$ [Fig. 1(c)]; in this arrangement, in which PL emitted

along the growth direction was monitored, the emitted light is unpolarized and the transitions cannot be separated by circular polarization analysis). The values of $g_{\text{exc}}$ (Table I) now correspond approximately to the $g$-value of an electron (in bulk material $g_r=1.12,17,18$ and in strained material with $S=13$ meV, when $\theta=90^\circ$, $g_r=1.15$).\textsuperscript{16}

III. MODEL AND APPLICATION TO ZnSe

We shall see that the origin of the $K_r$-dependence of $g_{\text{exc}}$ is due to mixing between the 1S-like heavy-hole exciton ground state and the higher lying $P$-like light-hole exciton states. The mixing is a result of the terms in the valence band Hamiltonian which cause the dispersion to depart from simple parabolic form. This Hamiltonian can be written, following Luttinger,\textsuperscript{14} as

$$-\hbar^2/2m_0 \left( \gamma_1 + \frac{1}{2}\gamma_2 \right) J_z^2 - \gamma_2 \hbar^2/2m_0 \left( k_x J_y^2 + k_y J_x^2 + k_z J_x^2 \right)$$

$$- 2\gamma_2 \hbar^2/2m_0 \left\{ \left\{k_x J_x \right\} + \text{cycl.perm.} \right\} - 2\mu_{gq} \vec{J} \cdot \vec{B}$$

$$- 2\mu_{gq} (B_x J_x^3 + B_y J_y^3 + B_z J_z^3), \quad (4)$$

where $\vec{k}$ is the wave vector of the hole and $\{J_x, J_y\} = \{ (J_z + J_z), J_z \}$ etc. The directions $x, y, z$ refer to the crystal [100], [010], and [001] axes. The quantities $\gamma_1, \gamma_2, \gamma_3, \kappa$, and $q$ are the (dimensionless) Luttinger parameters; $m_0$ is the electron rest mass; we shall assume that $\kappa$ is much larger than $q$, so that the heavy-hole $g$ value is given by $g_{\text{HH}} \sim -6\kappa$. The electron-hole exchange interaction has been omitted from Eq. (4) since it is small \cite{about 0.4 meV (Ref. 19)} and in any case does not affect the Zeeman splittings for $\theta=0$.

When dealing with excitons in the c.m. approximation, it is convenient \textsuperscript{6-8} to replace $H^{(0)}(\vec{k} )$ by $H^{(0)}(-\vec{p} \cdot \vec{h} + e\vec{A} \cdot \vec{h} + \beta \vec{k})$. Here, for (B along z), $\vec{p}$ is the momentum operator for the electron within the exciton (equal to minus that of the hole) and $\beta=m_{\text{HH}}/(m_e+m_{\text{HH}})$, where $m_e$ and $m_{\text{HH}}$ are, respectively, the electron and heavy-hole effective masses. The vector potential $\vec{A}$ is given \textsuperscript{6-8} by $\frac{1}{2} \vec{B} \times \vec{r}$, where $\vec{r}$ is the electron-hole separation.

For general directions of the magnetic field and of the translational wave vector, the presence of the terms that involve $\gamma_2$ and $\gamma_3$ makes it impossible to separate the center of mass and internal motions, so that the hydrogenic envelope functions become mixed (this point will be discussed in detail elsewhere).\textsuperscript{20} For the particular case of (001) wells, it is the terms that involve $\gamma_3$ that lead to the changes in the exciton g value.\textsuperscript{2}

As a result, it is shown in Ref. 2 that the 1S HH ground states with $m_y=\pm 1/2$ and $m_z=\pm 3/2$ are mixed with $nP$ states with $m_y=\pm 1/2$, $m_z=\pm 1/2$, and $m_z=\pm 1$, where $m_y$ is the orbital quantum number. The matrix elements involved are on the form $|M_z|=(a+bb \cos \theta)K_z$; respectively, where $a$ and $b$ are both proportional to $\gamma_1$ [see Eq. (5) of Ref. 2].

The energies of the ground states are depressed by amounts $(a \pm bb \cos \theta)/\Delta E_0$, where $\Delta E_0$ is the energy difference between the unperturbed $nP$ LH and 1S HH state, given by

\[ \Delta E_0 = \frac{1}{2} \frac{1}{m_0} \left( \frac{1}{2m_{\text{HH}}} - \frac{1}{2m_{\text{LL}}} \right) K_z^2. \]

The presence of the cross terms linear in $B$ thus leads\textsuperscript{2} to contributions to the g value of

\[ \delta g_1 = \frac{24\gamma^2\hbar^2 \beta^2 \cos \theta}{m_0} \frac{1}{\Delta E_0} \frac{w_n}{w_n}. \]

where $w_n=-(nP, p_\parallel \partial / \partial x |1S)a_{\text{exc}}$ and $w_n=(nP, p_\parallel |1S)a_{\text{exc}}$.\textsuperscript{19}

There are similar contributions from all $nP$ states, including $P$-like states in the continuum.\textsuperscript{2} For the present ZnSe layers, for which the strain splitting $S=13$ meV, we take $\gamma_1=2.45$, $\gamma_2=0.61$, $\beta=0.20$ meV,\textsuperscript{17,18} and $m_e=0.145m_0$.\textsuperscript{19} To fit the extrapolated value for $g_{\text{exc}}$ for $\theta=0$ at a notional value of $K=0$, we take $g_e=1.12$ (Refs. 17 and 18) and $g_{\text{HH}}=0.42 \pm 0.20$. The calculated curve for these values is shown in Fig. 5 and produces excellent agreement with experiment with a value of $\gamma_1=0.98 \pm 0.05$, which compares with the value of $1.11 \pm 0.11$ from Ref. 21. The value of $g_{\text{HH}}$ corresponds to $\kappa=-0.07$ in Eq. (4).

When the field is at a right angle to the growth direction ($\theta=90^\circ$), there are no contributions to the exciton g value due to the mixing [see Eq. (6)] and the heavy-hole g value also becomes zero. As a result, the exciton g value becomes equal in magnitude to that of the electron, as is observed experimentally as in Fig. 4 [see also Table I; the sign of $g_{\text{exc}}$ changes as $\theta$ goes to $90^\circ$, in accordance with Eq. (3)]. For the higher lying states in the well, the magnitude of $g_e$ is seen (Table I) to become significantly larger than the bulk ZnSe value of 1.12. This is ascribed to the finite depth of the quantum well and penetration of the wave functions into the barrier regions, as discussed in Ref. 16.

In the three specimens, we have also been able to determine the values of $g_{\text{exc}}$ for the $N=1$ light-hole states, the values being on the order of 0.5. These values will be af-
fected both by the proximity of the relevant part of the dispersion curve to the region where polariton effects are important and, as for the heavy holes, by motion-induced mixing with other excited states. Calculation of these parameters is, however, beyond the scope of the present article.

The terms in $[M_z]^{12}$, which involve $B^2$, lead to $K_z$-dependent negative contributions to the diamagnetic shifts. These contributions contain the factor $a_{\text{exc}}^{-2}$. We take $a_{\text{exc}}=3.5 \text{ nm}$ and find that, at the highest value of $K_z$ ($6 \times 10^6 \text{ cm}^{-1}$) that could be studied, the decrease (relative to the value at $K_z=0$) in the diamagnetic parameter $D$ due to the mixing is calculated to be $9 \times 10^{-7} \text{ eV T}^{-2}$. This is at the limit of experimental detection, but is in agreement with the decrease on order $10^{-6} \text{ eV T}^{-2}$ given in Table I. In the case of CdTe, the much larger exciton Bohr radius ($\approx 7.2 \text{ nm}$ (Ref. 2)) allowed this motion-dependent decrease in $D$ to be much more clearly observable.

IV. CONCLUSIONS

The observations above provide strong confirmation that the magnetic properties of excitons are affected strongly as they acquire kinetic energy. In the center of mass approximation, the origin of the effect is motion-induced mixing between the $1S$ exciton ground state and excited states of $nP$ form. The mixing is caused by the $\gamma_1$ terms in the description of the valence band dispersion curve. In the case of CdTe, a model for this process led to a successful quantitative description of the motion-induced changes in the magnetic moments and of the diamagnetic shifts. As a consequence, the magnetic moment of the exciton is not simply the sum of the magnetic moments of the electron and hole, but contains motion-induced contributions, which can easily dominate the contributions from the individual charge carriers.

In the present paper, we have shown that this model accounts equally well for the detailed properties of a second semiconductor, ZnSe, with a value of $\gamma_1$ of $0.98 \pm 0.05$ for the Luttinger parameter $\gamma_3$ in excellent agreement with the value of $1.11 \pm 0.11$ determined from two-photon magneto-absorption spectra.\textsuperscript{21} ZnSe differs from CdTe is several respects: in particular, the sign of the $g$ values of the individual charge carriers in ZnSe are opposite to those in CdTe. The combined data for the two materials thus show unequivocally that it is the motion-induced mixing process that leads to the observed changes in the exciton $g$ value, rather than, for example, quantum confinement changes in the $g$ values of the individual electrons and holes. In other words, the behavior is characteristic of the exciton as a whole, rather than of its constituent particles. The success of the model in describing the properties of these two different semiconductors thus provides convincing evidence for the universality of motion-induced changes in exciton magnetism.
